Suitable coatings that will provide protection for a minimum of 2 years should be applied by the manufacturer over rods and couplings. An oil-soluble coating is preferred, and it should be maintained by reapplication during storage. Used sucker rods should be cleaned and coated before storage.

Sucker rods should be protected when pulled during workover operations. A batch of oil and inhibitor solution can be pumped into the tubing before pulling, or the rods can be coated after pulling.

Couplings should be dipped in or brushed with an oil-inhibitor mixture before makeup. Care should be taken so that the amount of inhibitor added is not excessive. Thus, proper make-up can be performed.

It is recommended that inhibitor be added to the tubing when the rods are run in the hole for initial filming. When the well is placed in production, one tubing volume of fluid should be circulated.

Once the well is in production, an inhibition and monitoring program should be initiated. An inhibitor is selected by testing for efficiency, usually with laboratory tests. These tests may include a wheel test, in which the inhibitor is added to bottles or high-pressure cells, rotated in a heated oven, and compared to an untreated control for percent protection and lack of pitting. Other tests include the stirred flask test and flow tests. All of these tests are designed to duplicate field conditions or to determine response to different corrodents under specified parameters.

There are several methods by which the cell can be treated. These include batch, continuous, and squeeze treatment, which are covered in the discussion “Inhibitors” in this Section and are discussed in the article “Corrosion Inhibitors for Oil and Gas Production” in *Corrosion: Fundamentals, Testing, and Protection,* Volume 13A of *ASM Handbook.* Other methods include tubing displacement after unseating the pump and the use of weighted inhibitors, sticks, or encapsulated inhibitors.

Downhole hydraulic pumps operate by pumping clean crude oil with a surface engine-driven pump down a string of tubing to operate a downhole hydraulic pump. The downhole pump lifts one barrel of fluid for each barrel of power fluid. The power oil is comingled with the produced fluid and separated on the surface. Problems can arise if the power oil carries water and solids or if CO_2, H_2S, or organic acids are present. The use of corrosion-resistant alloys and inhibitors can alleviate corrosion. Inhibitors are continuously added to the power fluid at the surface pump suction. Scale inhibitors and demulsifiers can also be added to the power fluid to prevent scale deposition and carryover of water into the power fluid.

In gas-lift wells, pressurized gas is injected into the annulus and through a gas-lift valve into the tubing. Fluid is displaced upward and out of the well by the gas. The process is repeated in batches or slugs in an intermittent system, or as a steady stream in a continuous-flow system. The velocities and turbulence encountered may increase corrosion initiated by H_2S and CO_2. Corrosion-resistant alloys can be used in gas-lift valves, and tubing can be protected by inhibitors.

Inhibitors are added into the lift gas at the surface and are carried with the gas stream into the tubing. Protection is provided above the lowest gas-lift valve. If corrosion occurs below the valve, batching or squeezing may be required for complete protection. The inhibitor selected is usually oil soluble and water dispersible, and it can be diluted with hydrocarbon to assist in carrying it downhole.

Flowing Wells

Corrosion problems in flowing wells are somewhat different from those encountered in artificial lift wells in that velocity becomes an important factor, and higher pressure lead to higher CO_2 partial pressures. Treating methods are more limited because of completion requirements.

Gas condensate wells may produce gas, hydro-carbons, formation water, acid gases (CO_2 and H_2S), and organic acids. If the producing conditions allow liquid water to be produced or to condense on the tubing, corrosion is likely.

In wells producing formation water, corrosion may occur anywhere in the tubing string, wellhead, and flow line. Temperatures in the wellbore will affect the corrosion rate, and flow velocities also affect metal loss. The salinity of the water and acid gas content are factors in corrosion rates.

Wells that produce no formation water will corrode where the dew or condensation point of water is reached and free water condenses on the tubing . The water will dissolve CO_2 or H_2S and become corrosive.

Carbon dioxide corrosion is particularly damaging in condensed water. Dissolved CO_2 can lower the pH of water to less than 4.5 at CO_2 partial pressures of 69 kPa (10 psi) and temperatures of 75 °C (170 °F). Carbon dioxide corrosion can cause severe pitting when conditions of temperature and salinity form iron carbonate scale in a noncontinuous or spotty layer. Organic acids increase CO_2 corrosion rates by dissolving iron carbonate scale and by lowering bicarbonate content so that further iron carbonate scaling is prevented.

H_2S also dissolves in water, although the pH reduction is not as great as that found with CO_2. Metal loss and pitting, along with hydrogen embrittlement and sulfide stress cracking, may be present.

Oxygen is not present in the production stream, and it is not a problem unless it is introduced into the system by corrosion treatments. It then can have some effect on corrosion and will cause pitting of ferritic stainless steels.

Materials Selection. Most gas wells are completed with low-alloy steels for economic reasons. These steels will perform satisfactorily in most wells, and the application of coatings and the use of corrosion inhibitors permit their use in severe environments of high temperature, pressure, and CO_2 content.

Many Tuscaloosa Trend wells completed with carbon steel tubing are producing with no corrosion failures when coated and inhibited. Producing conditions range of 230 °C (450 °F) bottom hole temperature, 124 to 138 MPa (18 to 20 ksi) pressure, and CO_2 content of 5% or more. Hydrogen sulfide is also found in some wells at concentrations of 20 to 50 ppm.

Alloy Tubulars. When conditions and economics warrant, corrosion-resistant alloys can be used. Steel with 9% Cr and 1% Mo has low corrosion rates up to 100 °C (212 °F). Higher corrosion rates and pitting become a problem at higher temperatures. The partial pressure of CO_2 is not a factor at temperatures below 240 °C (465 °F). Steel with 13% Cr is effective up to 150 °C (300 °F). Oxygen will cause severe pitting of 13% Cr steel; therefore, chemical injection systems must be kept oxygen free by an inert gas blanket on storage tanks.

If H_2S is present, 9% Cr and 13% Cr steels an be used at hardnesses below 22 HRC. Of the two, 13% Cr steel is more resistant to chloride cracking.

Coatings. Low-alloy steels can be coated for corrosion resistance. Coatings include baked-on phenolics, epoxies, and polyurethanes with fillers to give the required thickness, coating integrity, and corrosion resistance. Proper application is required for an intact coating that conforms to requirements. Tubing surface preparation, application methods, coating thickness, and holiday detection are part of the inspection and quality assurance process.

Joints and connections should be designed so that the continuity of the coating is unbroken. The first few threads inside the female connection and the pin nose must be coated. A compression ring can be installed to ensure joint integrity.

Special care must be taken when the wireline operations are carried out in the coated tubing. Coatings are easily damaged or scratched, and once the coating is broken, corrosion ad disbonding of the remaining coating can take place.

Wireline guides and running speeds of less than 0.5 m/s (100 ft/min) will minimize damage. A corrosion inhibitor should be used directly after wireline operations. The wireline tools should not have sharp edges and should be plastic coated. Wireline centralizers should also be used.

Coatings are also subject to disbondment if pressures are released suddenly. Gases can penetrate the coating, and when a sudden pressure drop occurs, the gases will expand and lift the coating.

Inhibitors. Corrosion inhibitors are an effective means of corrosion control, and they are required in highly corrosive environments in which carbon steel is used. They are needed even if the tubing is coated, because a holiday-free coating does not exist. Combination coating-inhibitor procedures are particularly effective.

The most commonly used inhibitors function by forming a film on metal surfaces that stops the flow of corrosion current. Nearly all inhibitors are fatty amines or quaternary ammonium compounds. The nitrogen in the molecule possesses a strong cationic charge and is chemically absorbed onto anodic sites on the metal surface. Cross-bonding of the film and the attraction of a layer of oil aid in isolating the surface.

Inhibitors are selected for several characteristics. The major consideration is the lowest corrosion and pitting rate, followed by film persistence, nondamaging to producing formations when squeezed, and minimal system upsets due to emulsion stabilization.

Once a inhibitor is selected, a treating method is used that fulfills the system requirements. Several methods are commonly used to treat flowing wells; batch treating, continuous injection, and squeezing will be discussed below.

Batch treating involves the intermittent addition of relatively large quantities of inhibitor solution to the annulus or down the tubing of a gas condensate well. A batch treatment in a flowing well consists of dumping a solution of inhibitor in condensate or diesel fuel down the tubing, shutting the well down to allow the inhibitor solution to fall to the bottom, and repeating at a set interval. The disadvantage of this treatment is that the inhibitor may not go to bottom. The tubing may contain up to 50% of its volume of water and oil, and the bottom of the well below the static shut-in fluid level may not be treated.

A method of treatment that ensures that the batch will reach the bottom of the well is tubing displacement. A batch of inhibitor in oil, usually one-third of the tubing volume, is pumped in, and enough condensate or oil is pumped in to displace the batch to bottom. The well is shut in for a few hours and brought back on production. This ensures that the tubing is treated all the way to bottom. Tubing displacements may last from a few days to a month or so, depending on the severity of the corrosion problem, the produced fluids, the flow velocity, and the ability of the inhibitor to form a persistent film.

Nitrogen or another gas can be used to displace the inhibitor solution instead of liquid. This is of value if the well has a low bottom pressure, because filling the tubing may permanently stop production or "kill" the well. It is also a value where volumes of oil cannot be easily moved around. A variation of the nitrogen batch is to atomize the inhibitor solution into the nitrogen as it is pumped into the well. The inhibitor selected should have good film persistency.

Continuous injection consists of constant addition of small concentrations of inhibitor into a producing well. The chemical can be added into a chemical or capillary string or down the annulus of a packerless completion. Chemical injection valves in a side pocket mandrel can be installed so that the solution can be pumped continuously into the annulus of a well with a packer.

In the Tuscaloosa Trend, wells were originally completed with a Y-block and kill string. This string was used for chemical injection. Wells were then completed with a packer and a chemical string, and later with a packerless completion where the inhibitor was added down the annulus.

In deep, hot wells, the inhibitor is added diluted in condensate. This is necessary because the gas is undersaturated with hydrocarbon. At high pressures, gas acts as a liquid and may strip the solvent from the inhibitor. The amount of condensate is calculated to saturate the gas. Some wells have been treated with a water solution or dispersion of inhibitor instead of condensate.

Capillary strings are small-diameter, armored tubing that is strapped to the outside of the tubing as it is run into the well. A surface tank, pump, and filter are installed. The filter is necessary to prevent particles from plugging the small-diameter tubing. Inhibitors must be selected that do not polymerize, because this would also plug the capillary.

A recent method of treating a well with a packer consists of using a perforating gun to shoot holes in the tubing. The inhibitor is pumped down the annulus and through the holes. This method is said to be more economical than recompleting the well.

Continuous treating of deep, hot wells requires an inhibitor that will not break down or form a gunk or char. This is particularly important in wells treated with a capillary string or down the annulus where the inhibitor solution must remain for an extended period of time. A surface filtering system is also required for capillary string treating.

The deep, hot wells in the Tuscaloosa Trend require an inhibitor that will withstand temperatures to 230 °C (450 °F) without breaking down. Although the chemical strings in the wells that have not been converted to packerless completions are large in diameter (25 to 50 mm, or 1 to 2 in.), plugging problems may occur. Most of this is due to salt plugs, and the condensate has a natural fouling tendency. Therefore, any tendency to form an insoluble residue by the inhibitor adds to the problem. A high-pressure high-temperature stability test is run in lease fluids to ensure the stability of the inhibitor. The amount of inhibitor required will range from 10 to 100 ppm under most conditions. Extremely corrosive wells may require more.

Squeezing involves placing an inhibitor solution into the producing formation far enough back from the wellbore so that a continuous feedback of inhibitor is obtained. The squeeze is sized so that a predetermined life is obtained. Field crude, condensate or diesel oil are commonly used as diluents for squeeze treatment.

The inhibitor must have the proper solubility in the diluent, and it must not form a gunk or severe emulsion with produced water. Either condition could cause temporary or permanent loss of permeability and subsequent loss of production. A core test is sometimes conducted to select an inhibitor for a tight, or fairly low permeability, formation. Film persistence is not as important as continuous protection, because inhibitor will be present in the production stream at all times.

In some reservoirs, condensate is above critical temperature and therefore exists as a gas. This condition is known as a retrograde reservoir, because when the pressure is lowered, condensate comes out of solution with the gas, rather than the normal condition in which lowering the pressure vaporizes the condensate.

A dry reservoir that contains no liquid condensate should not be squeezed. Permanent loss of relative permeability will occur, and gas production rates and hydrocarbon recovery will be decreased.

One common objection to squeezing is that inhibitors are cationic and will oil-wet the formation. The wetting characteristics of a surface-active material are based more on its hydrophilelipophile balance (HLB), which is a measure of tendency of the inhibitor to water-wet or oil-wet a surface, than on reservoir properties.

The HLB is determined by the size and type of oil- or water-soluble parts of the molecule. Nonionic surfactants are used to oil-wet metals in lube oils and are used to water-wet materials in cleaners. Sulfonates are excellent water wetters, while other sulfonates are used as oil wetters. Cationics follow the same rules. In fact, polyamines and quaternary ammonium compounds are used in workover fluids to water-wet silicates.

It is most likely that some oil wetting of the formation occurs (the inhibitor goes into the oil in the reservoir). This is what causes a squeeze to work. Nevertheless, any change in the wettability of the formation is reversible. The formation immediately begins to return to its original state once the wetting agent is removed or begins to dissipate. Natural or simulated core tests can be conducted to ensure that no formation damage will occur from the inhibitor.

The loss of production that can from a squeeze is due to the formation of a stable emulsion in the area immediately adjacent to the wellbore. This emulsion is nearly always a water-in-oil emulsion, which is very viscous. The high-viscosity emulsion will not flow through the pore throats. Emulsion blocking can be prevented by proper inhibitor selection and by adding demulsifiers to the squeeze.

A typical squeeze can be performed in the following manner. First the amount of inhibitor required for the projected life of the squeeze should be calculated:

$$V = \frac{42 \cdot P \cdot D \cdot 3\ (\text{ppm})}{1\ 000\ 000} \qquad \textbf{(Eq 7)}$$

where*V* is the volume of inhibitor (gallons), *P* is the total daily production in barrels (including both oil and water), *D* is the expected squeeze life, and ppm is the amount of inhibitor feedback desired (this is multiplied by 3, because it is assumed that only one-third of the inhibitor will remain in place that will desorb and feed back). The remaining five steps are as follows:

- Dilute the inhibitor with crude, condensate, or diesel oil to 10%
- Pump a spearhead of 5 to 10 barrels of oil with 19 L (5 gal) of demulsifier
- Pump the main body of the squeeze treatment into the formation
- Overflush with one tubing volume plus one day's production volume of oil (19 to 38 L, or 5 to 10 gal, of demulsifier can be added to the overflush)
- Shut in the well for 12 to 24 h

This procedure can be modified to suit the requirements of a particular situation.

In many applications, the amount of overflush needed to place the inhibitor properly is too large, or filling the tubing may kill a low-pressure flowing well. The use of nitrogen instead of hydrocarbons overcomes these restrictions.

In a nitrogen squeeze, the inhibitor solution is displaced downhole and into the formation with an equivalent amount of nitrogen. This leaves the tubing empty and charges the formation so that it flows back readily.

This procedure can be modified so that the inhibitor solution is atomized into the nitrogen as it is injected. Both of these procedures have been used with excellent results. The wells could be returned to production in 4 h, and due to the charging effect, the increased production rates for a day or so compensated for the production loss during the squeeze.

Monitoring

Once the well, line, or vessel is treated, it is necessary to evaluate the effectiveness of the treatment program and to determine when to re-treat or change dosage levels. The methods used include iron counts, weight loss coupons, test nipples and spools, electrical resistance and linear polarization methods, and waiting for the tubing to fail. This last method is not popular with operators. However, the collection of failure data, such as tubing failures, is a valuable source of monitoring information.

Iron counts consist of taking a representative sample of produced water and testing for iron content. The sample must be representative. The iron counts can be plotted for easier understanding. Some computer programs will present iron counts on a computer plot in color. Care must be taken so that the iron from the formation is not assumed to be metal loss from the tubing. Some of the deep, hot Tuscaloosa Trend wells produce water with over 100 ppm of iron. A base count should be conducted on a downhole sample, if possible.

Corrosion coupons may be flat or cylindrical and may be installed in any accessible location. It must be remembered that coupons measure corrosion only where they are placed. Coupons show corrosion that has already taken place, and a single coupon will not show whether the corrosion was uniform or occurred all at once.

Different types of coupon holders or chunks are used, depending on the system, the pressure, the location, or other factors. Most coupons are run in a 25- or 50-mm (1- or 2-in.) threaded plug. Flat coupon holders hold two coupons, while cylindrical coupon chunks may contain eight or more. The multichuck coupons allow a coupon to be pulled at intervals to see if the corrosion rate is uniform or not.

High-pressure systems require a special coupon check and insertion device. The insertion tool fits into a special attachment on the pipe or vessel that has a high-pressure chamber with a valve on each end. The inner valve is closed, the retrieval tool inserted, and the inner valve opened. The tool is then run in and left. The procedure is reversed to remove the coupon.

The industry guide for preparing, installing, and interpreting coupons is NACE standard RP-07-75. The primary consideration is that all coupons be treated exactly alike. A method of preparation that does not alter the metallurgy of the coupon is required. Grinding and sanding of coupons should be controlled to avoid metallurgical changes and to provide a consistent and reproducible surface finish.

Coupons should be handled carefully and stored in noncorrosive envelopes until they are installed. Rust spots caused by improper handling, fingerprints, and so on, may initiate a pit that is not representative of the system being evaluated. Prior to installation, the weight, serial number, date installed, name of system, location of coupon, and orientation of the coupon and holder should be recorded. The coupons are left in the system for a predetermined number of days and then removed.

When the coupons are removed, the serial number, date removed, observations of any erosion or mechanical damage, and appearance should be recorded. A photograph of the coupon may be valuable in some cases. The coupons should then be placed in a moisture-proof envelope impregnated with a vapor phase inhibitor and taken immediately to the laboratory for cleaning and weighing. The coupons can be blotted (not wiped) dry prior to placing in the envelope.

The laboratory receives the coupon and inspects, cleans, and weights it. A report is issued showing the thickness loss, any pitting observations, and any other observations of interest.

Electrical resistance probes function by reading the resistance to current flow of a thin loop of metal installed in the system. The loop of metal is part of an electrical bridge circuit. As the loop corrodes and loses cross-sectional area, electrical resistance increases, and the current flow decreases. This unbalances the bridge and reads out directly on a meter. It may also be recorded on a strip recorder. As the reading changes, the points are plotted on a graph. The slope of

the line is translated into a corrosion rate. The slope will change when a well is treated or when any event occurs that changes corrosion rate.

The metal loop is fragile, and it can broken if foreign objects, chunks of scale, and similar obstructions are present in the flow. The loop may become coated with paraffin and will not give a true reading. Pitting rates cannot be determined with a resistance probe.

Linear polarization instruments apply a voltage to a pair of electrodes, compare it to a reference voltage, and then read and record the current flow. The voltage is impressed in a forward direction until breakdown occurs, that is, until a small increase in voltage causes a large increase in current. The voltage is increased some distance past breakdown, and the polarity is reversed. The positive electrode then becomes the negative electrode.

The voltage is then increased in the opposite direction past the original voltage starting point. These voltages are recorded and plotted continuously on graph paper. The position and shape of the curves will show the corrosion rate, maximum corrosion rate, and the influence of oxygen.

The principal advantage of this instrument is that a corrosion rate can be determined immediately, and a pitting rate can be measured without waiting a month or so to pull coupon or calculate a slope with a resistance probe. Probe locations are very important, because the probe must be immersed in water to give an accurate reading. Probes can become coated with paraffin and will show an erroneous corrosion rate. They should be located in the bottom of a line or in a bypass loop so that they are continuously immersed in water. The probe may also short out if a piece of metal is across the probe or if corrosion by-products and other deposits collect on the probe.

A test loop can be installed in a system for better control. A test loop is simply a bypass with valves for controlling flow, and it may contain weight loss coupons as well as probes. The system can be monitored, and different inhibitors can be evaluated at the same time.

A caliper survey can be conducted to determine if pitting and general metal loss have been halted. The caliper log can be easily compared with a long run before the treatment is begun.

Other monitoring methods include hydrogen probes, galvanic probes, and electromagnetic logging devices. Chemical analysis of produced water for alloying metals, such as manganese and chromium, can be conducted.

Collection of Field Data. It is important to collect and chart failure rates. Some failures may occur over a period of time and may erroneously indicate that the treatment is not effective. However, through proper charting and comparing with previous failure rates, the effectiveness of proper treating will be shown.

Corrosion in Secondary Recovery Operations

Secondary recovery, or waterflooding, generally increases the corrosion problems in existing producing wells. It also creates a new set of problems because of the facilities required to reinject the produced water. This section will discuss the corrosion problems that are specific to the various types of environments or equipment used in secondary recovery, that is, producing wells, producing flow lines, separation facilities, tanks, injection pumps, injection lines, and injection wells. Although not specifically addressed, disposal wells (wells that are used for produced water disposal rather than reinjection into producing formations) are considered to be the same as injection wells. Corrosion mitigation methods and guidelines are then discussed for each type of environment.

Types of Corrosion Problems

Producing Wells. The corrosion mechanisms in secondary recovery are similar to those in primary production. The primary causes of corrosion are dissolved acid gases (H_2S and CO_2) in the produced fluids. Naturally occurring organic acids are often present and can aggravate H_2S and CO_2 problems. Corrosion will generally increase in secondary recovery because of the large increase in water production caused by waterflooding. The fraction of water produced, or water-cut, may increase to 90% or more. This increases the potential for corrosion, because more of the metal surfaces may be water-wet rather than oil-wet. The increased volume of water can increase pumping equipment stresses. Increased stress levels can cause more corrosion fatigue related failures.

Corrosion mechanisms may change during waterflooding. For example, a normally sweet field (that is, the produced fluids contain no H_2S) may begin to produce H_2S because of the growth of sulfate-reducing bacteria in the formation. This can cause unexpected corrosion related to the H_2S, pitting under sulfate-reducing bacteria deposits, or failures from sulfide stress cracking in high-strength materials.

Mineral scale problems, such as the deposition of $CaCO_3$, $CaSO_4$, or $BaSO_4$, may increase during waterflooding. This is usually the result of changes in the formation water brought about by injecting waters from sources other than the original reservoir. Although not strictly a corrosion problem, scale deposition can cause increased failures due to wear and under-deposit corrosion.

Producing Flow Lines. Corrosion mechanisms in producing flow lines are similar to the mechanisms downhole, but generally occur at a lower rate because temperatures and pressures are lower at the surface. Corrosion is often localized to the bottom of flow lines if flow rates are low enough to permit water stratification, which allows the bottom of the line to be continuously water-wet. Under-deposit corrosion and sulfate-reducing bacteria related pitting are often severe under sludge or scale deposits that accumulate in the low flow rate lines.

Oil/Water Separation Facilities. Corrosion in these facilities is normally related to attack by corrodents in produced fluids and deposit-related problems. Separation facilities are unique in that they often use heat to aid in oil/water separation. Heat transfer surfaces are usually subject to mineral scale deposition because of solubility changes caused by temperature increases. Scale deposition can result in severe under-deposit corrosion because metal surface temperatures increase due to the reduced heat transfer. Creep rupture failure can occur in direct fired heaters if deposition is severe enough to cause very high metal temperatures. Some separation equipment is open to the atmosphere, thus allowing oxygen contamination of the produced fluids and causing increased corrosion in equipment handling the water phase.

Tanks/Water Storage. Tanks are subject to corrosion by acid gases (CO_2, H_2S) carried over with the produced water. Under-deposit corrosion can be severe under accumulated sludge and debris in tank bottoms. These deposits are also prime areas for the growth of sulfate-reducing bacteria. Tank roofs often fail because of condensation. As water condenses on the roof, it will absorb acid gases from the tank fluids. This can cause severe pitting. Oxygen contamination often occurs in tanks. Obviously, open tanks are subject to contamination. Contamination can occur in normally closed tanks if hatches and vent systems are poorly maintained. Although oxygen can be somewhat corrosive by itself, its primary role in waterflood system corrosion is to significantly increase the rate of attack of other corrodents already in the system.

Injection pumps can fail by normal corrosion mechanisms as well as by cavitation and erosion. Pump intake piping design must take into account the presence of dissolved H_2S and CO_2 in the water. These gases can affect net positive suction head calculations. If sufficient net positive suction head is not provided, cavitation can occur. Erosion and erosion-corrosion can occur because of solids in the water. Solids normally consist of corrosion products, formation fines, and mineral scale particulates. Alloy materials such as type 304 and 316 stainless steels are often used for pump internal parts. These alloys can fail by chloride SCC in produced brines if temperatures are above 52 to 65 °C (125 to 150 °F). Pumps are subject to cyclic stresses. Corrosion fatigue failure can occur at sharp changes in cross section, grooves, and at pitted areas, all of which cause stress concentrations.

Injection Flow Lines and Wells. Corrosion mechanisms are generally the same for producing well flow lines and tubulars, that is H_2S, CO_2, and organic acids. Under-deposit problems in the bottoms of lines and under mineral scales can also occur, as can problems with sulfate-reducing bacteria. Oxygen contamination will greatly accelerate all but the sulfate-reducing bacteria mechanism. Sulfate-reducing bacteria corrosion can still occur even in aerated systems because localized areas under scales, sludges, or aerobic bacterial slimes can become anaerobic and thus support the growth of sulfate-reducing bacteria.

Injection wells and flow lines may require periodic acidizing to reduce pressure drops and to restore the injectivity lost because of the buildup of corrosion products and mineral scales. Severe corrosion can occur if acidizing fluids are not properly inhibited and flushed from the system.

Corrosion Mitigation Methods

Producing Wells. Corrosion control methods for secondary recovery are typically the same as those used for primary recovery. The particular method implemented will depend on the type of production method used (that is, beam lift, electric submersible pump, or gas lift), well design, and the economics of the individual situation.

Corrosion inhibitors are widely used to protect tubulars and other downhole equipment in all types of producing wells. The most common methods of sending the inhibitor downhole where it can protect the well equipment are referred to as squeeze treatment, batch treatment, and continuous treatment (see the discussions "Inhibitors" and "Primary Production" in this Section). References 60 and 61 contain detailed descriptions of the various methods as well as guidelines for selecting a particular method. Regardless of the method used, the inhibitor must be effective against the particular type of corrosion occurring, that is, H_2S, CO_2, or both. Laboratory tests should be performed if there are any questions regarding the effectiveness of the inhibitor for a given type of corrosion.

The type of corrosion inhibitor used (oil-soluble, oil-insoluble, water-dispersible, water-soluble, and so on) will depend on the treatment method. Batch treatment is a widely used method of treatment for beam lift wells. Corrosion inhibitor solutions are periodically injected into the casing-tubing annulus and flushed to the bottom of the well with produced fluids, diesel oil, or water. A water-dispersible inhibitor is normally used because of the high percentage of water in the well stream. However, increased water dispersibility can cause problems with oil/water separation because of the tendency for dispersion chemicals in the inhibitor to cause emulsions to form. Tests should be performed with actual well fluids to determine the emulsion tendency of the particular inhibitor being considered for use. (Often, any one of several inhibitors may be able to provide the necessary corrosion protection; however, there will be vast differences in emulsion formation.

Continuous injection of inhibitor may be necessary for wells with high fluid levels in the annulus above the pump. Water-soluble inhibitors are normally specified for this type of treatment. Studies have shown that continuous treatment may not be as effective as periodic batch treatment under most conditions (Ref 60). Emulsion problems are sometimes worse with water-soluble inhibitors than with oil-soluble or water-dispersible inhibitors because of the increased use of surfactants in water-soluble inhibitors.

The frequency of treatment and the quantity of inhibitor used will generally have to be increased during secondary production. In general, it is more effective to increase the frequency of inhibition (assuming a batch treatment procedure is used) rather than the quantity, although both may need to be adjusted in some cases. Treatment should be adjusted on the basis of corrosion-monitoring results and well equipment life. Corrosion monitoring can be accomplished in a variety of ways. Corrosion coupons installed in flow lines near the wellhead are the most common. Downhole monitoring is more difficult. Preweighed, short (0.6 m, or 2 ft) sucker rods can be used as downhole corrosion coupons, as can short joints of production tubing. Information on the preparation, installation, and evaluation of corrosion coupon data is provided in NACE RF-07-75.

Downhole equipment should be carefully examined for signs of corrosion whenever it is removed from the well. The occurrence of sucker rod failures is a common measure of downhole inhibition effectiveness in rod pumped wells (Ref 61). The number of failures that can be tolerated will depend on the economics of each producing situation. A general guideline is one corrosion-related failure per well per year. It should be remembered that corrosion fatigue failures of sucker rods are a function of corrosion and stress. Therefore, heavily loaded rods will tolerate less corrosion before failure than rods with lower stress levels.

Corrosion inhibitors are less effective in sucker rod pumps because of wear. Corrosion-related failures are generally controlled by changing the pump metallurgy. Guidelines for selecting pump materials are provided in NACE MR-01-76. Galvanic corrosion problems can be quite severe in pumps and are best controlled by eliminating or reducing the extent of dissimilar metals in contact with each other in the pump. This also applies to coatings used for wear resistance, such as chromium and nickel plating. Rapid failure can often occur in underlying steel if these coatings become damaged by wear. If the wear resistance of chromium plating is required, it may be necessary to upgrade the base material to avoid galvanic corrosion problems.

Wear of sucker rod strings can be controlled through the use of centralizing rod guides. A variety of nonmetallic materials are molded on physically attached the sucker rod to prevent it from contacting the tubing. Welded or metal guides should not be used. Sucker rod couplings are normally coated with a corrosion-resistant alloy by flame spraying or similar techniques. This will provide both wear and corrosion protection. Similar coatings can be applied to the rods; however, these have not been widely used because of the high cost involved.

Fiber-reinforced plastic sucker rods can be used to reduce corrosion fatigue failures, however, their primary benefit comes from production concerns rather than corrosion. Corrosion inhibition is still necessary when FRP rods are used to protect the steel end connectors of the rod and steel well tubulars. In addition, steel rocks are not entirely eliminated from the string when FRP rods are used. Internal tubular coatings are not widely used in rod-pumped wells, because they rapidly fail from rod wear. Fiber-reinforced plastic tubing is not widely used for the same reason.

Electric submersible pump wells are treated in much the same way as rod-pumped wells. Electric submersible pump wells pose an additional problem in that the pump fluid intake is above the motor housing. This means that inhibitors injected into the annulus do not reach the housing. A variety of methods have been used to reduce the corrosion of housings, including applying corrosion-resistant coatings and selecting corrosion-resistant alloys for the housing. Special inhibitor injection systems using small-diameter tubing to release inhibitors below the motor have also been employed. Corrosion of electric submersible pump internal parts is not typically a problem because of the widespread use of corrosion-resistant alloys. Internal tubular coatings can be used with electric submersible pump wells, because they are not subject to wear. Fiber-reinforced tubing has found application in a limited number of electric submersible pump wells.

Gas-lift wells are commonly treated by atomizing inhibitor solutions into the lift gas. This can provide protection to he tubulars only above the lowest operating gas-lift valve. Internal tubular coating. FRP tubulars, and corrosion-resistant alloys can be used above or below the operating valve to provide corrosion protection.

Producing Flow Lines. Carryover from downhole corrosion inhibition is often sufficient to protect flow lines. In extremely corrosive conditions, additional inhibitor injection, either batch or continuous, may be required. Internal coatings can be used on flow lines; however, obtaining protection in the area of pipe joints can be difficult. A variety of methods have been developed to minimize damage to the coating even in welded lines. Fiber-reinforced plastic line pipe is becoming more widely used for flow lines, because it is inherently corrosion resistant. Polyethylene lines are also used in low-temperature low-pressure applications.

Oil/Water Separation Facilities. Supplemental inhibitor injection is often used to help protect these facilities. In addition, vessels such as separators are often internally coated. Organic coatings are normally used, but platings such as electroless nickel are also employed. Noble platings, such as electroless nickel, can cause severe galvanic corrosion of underlying steel if the coating is cracked or otherwise damaged. Internal cathodic protection with sacrificial anodes is also used in vessels. Internal baffles and other pieces can be fabricated from corrosion-resistant alloys. Corrosion-resistant alloy linings can also be used.

Heat transfer surfaces and vessel bottoms should be periodically cleaned of scale and debris. Scale inhibitors should be used if continuous scale-deposition problems occur. Chromium-containing steels (2.25 to 12% Cr) can be used for heat transfer surface in direct fired heaters to reduce the possibility of creep rupture failures in applications subject to severe scale formation. However, these materials can be rapidly attacked in the presence of H_2S. High-nickel corrosion-resistant alloys can also be used to help prevent under-deposit corrosion problems.

Tanks/Water Storage. Internal coating is a common method of protecting tanks. Organic coatings are typically used. Steel tank life is often extended by the use of FRP linings, especially tank bottoms. Both chopped and mat systems are used. A variety of nonmetallic liners have also been used. Fiber-reinforced plastic tanks are becoming more popular is smaller sizes. Internal cathodic protection can also be used, normally in conjunction with internal coatings. Tanks should be periodically cleaned to remove the accumulated sludge and debris that hinder normal corrosion control methods and promote under-deposit and sulfate-reducing bacteria problems.

Tanks are usually the first source of oxygen contamination in the injection system. Open tanks and pits should be avoided. Various methods of excluding oxygen in open tanks have been attempted. Oil layers are ineffective. Several floating systems have been developed that are useful to some degree, but are not totally effective. It must be remembered that as little as 0.01 ppm oxygen is sufficient to cause major increases in corrosion rates. Oxygen also renders many corrosion inhibitors ineffective. Closed tanks can also allow oxygen entry. Poorly maintained hatch seals and venting systems are notorious as sources of contamination. The optional method of excluding oxygen is to ensure that all openings to the tank are properly maintained and that a low-pressure inert gas blanket is used. Gas blanketing provides a slight positive pressure that will keep air from entering. Gas blankets can be part of the vapor recovery system, if used, or can be externally supplied from bottled gases, such as nitrogen.

Oxygen can enter the injection system in other ways. Often, additional water must be obtained to augment produced water volumes. Freshwater can be obtained from lakes, rivers, or wells drilled into aquifers. Seawater is used in offshore and coastal locations. All of these waters will have some amount of oxygen contamination. Severe corrosion can result if this contamination is not removed. Common removal methods include the use of chemicals or scavengers, such as sodium sulfite or ammonium bisulfite, and vacuum or gas stripping (see the discussion "Environmental Control" in this article).

Tanks are also excellent locations for the growth of sulfate-reducing bacteria. If tanks become contaminated with sulfate-reducing bacteria, they must be cleaned and sterilized with biocides. Cleaning is a necessarily, because it is impossible for biocides to penetrate adequately the large amounts of sludge and debris on the tank bottom.

Injection Pumps. Corrosion-resistant alloys are widely used in injection pumps and ancillary equipment. The particular choice of materials used will depend on the nature of the fluids handled and the type of pump involved. Specific material recommendations are provided in NACE RP-04-75. Caution should be exercised, because this specification does not address the temperature limitations of the materials. Chloride SCC can occur in 300-series stainless steels if they are used in saline waters above 52 to 65 °C (125 to 150 °F). Also, pitting of these materials can occur in aerated salt water if they are left stagnant in a pump. For example, it is common practice to have standby equipment piped into a system and to test the equipment periodically. Flushing the equipment with deaerated and inhibited freshwater is recommended to prevent pitting corrosion.

Flow Lines and Injection Wells. All potential corrosion mechanisms must be dealt with to obtain acceptable service lives of injection systems. This includes corrosion by dissolved acid gases, growth of sulfate-reducing bacteria, oxygen contamination, and scale/sludge deposition.

Corrosion inhibitors can be used to control flow line and injection well corrosion. Treatment is usually continuous, but batch treatment can also be used. Both oil-soluble/highly water-dispersible and water-soluble chemicals are used. Flow lines can be internally coated with organic coatings. Cement and other nonmetallic linings are also used. Fiber-reinforced plastic flow lines are widely used, even in high-pressure injection systems. The lack of an American Petroleum Institute (API) specification for high-pressure FRP line pipe and the lack of standardization in the FRP pipe industry have limited the use of these materials. Standardization of pressure rating methods and improved quality control of the products will greatly increase FRP use.

Injection well tubulars can be bare steel if corrosion inhibition is used. Internal coating is also widely used even with corrosion inhibition (see the discussion "Coatings" in this Section). Care must be taken when handling internally coated tubing to prevent coating damage. Special guides must be used when the tubing is installed to prevent damage to the pin nose. Makeup equipment must not deform the tubing enough to crack the coating. Standard API couplings are routinely internally coated in the standoff thread area. The recent advent of flush joint tubing connections using nonstandard couplings has helped to make internally coated tubing applications more reliable. The new connections help to seal the end of the tubing joints in the coupling. This has long been a problem area in internally coated tubing because it is easily damaged during handling and installation.

Corrosion-resistant alloy tubulars are used on some occasions, but their high cost is usually prohibitive. Fiber-reinforced tubing is used to some extent; however, again, the lack of standardization has been a limiting factor. Handling and makeup procedures are critical for successful fiber-reinforced tubing application. Many failures have resulted from overtorquing of FRP connections by crews used to handling steel tubulars. No reliable method has been developed for accurately predicting the long-term performance of FRP tubulars subject to both internal pressure and axial load.

Injection wells frequently require acidizing to restore injectivity. Typical acids used are 15% HCl and 12% HCl-3% HF. Severe corrosion can result if these acids are not properly inhibited. Corrosion inhibitors are available from acid service companies. Inhibitor concentration should be such that the corrosion rate of low-carbon steel is less than 245 g/m^2 (0.05 lb/ft^2) over the length of time the acid is to be in the well. It is good practice to ensure that the acid delivered to the job site actually contains the inhibitor and is the strength called for in the workover procedure. A simple test procedure for determining the presence or absence of inhibitor is given in API Bulletin D 15. This test is not designed to determine inhibitor effectiveness at well conditions nor to compare different inhibitors. Laboratory testing in necessary to establish inhibitor effectiveness.

Acid exposure can have a wide range of effects on the internal tubular coatings that may be present. Laboratory testing should be conducted if there is any doubt regarding the ability of the coating to withstand the acid exposure without damage. Fiber-reinforced plastic tubulars can also be damaged by exposure to mineral acids. Although tubing manufacturers do not prohibit acid exposure, they all recommend that temperatures and exposure times be kept to absolute minimums. The use of hydrofluoric acid in acidizing fluids is not recommended if FRP tubing is installed.

Carbon Dioxide Injection

Secondary recovery by waterflooding can greatly increase the amount of oil recovered over primary production, but may still leave up to 80% of oil in place in the reservoir. Tertiary recovery by injecting CO_2 will remove the oil not obtained by waterflooding. Carbon dioxide can be used at much lower pressures than other gases, such as nitrogen or methane, because it dissolves readily in some crudes and can cause up to a tenfold viscosity reduction in heavy crudes.

Oils with an API gravity of 25 or higher are candidates for miscible flooding. This process can recover oil from low-permeability reservoirs. Oils with gravities down to API 15 are recovered by an immiscible process based on oil swelling and viscosity reduction.

Carbon dioxide injection uses gas from fields that produce almost pure CO_2 from burning of lignite and recovered CO_2 from industrial combustion gases. These gases are purified and compressed, and in some cases, they are pipelines for hundreds of miles to the fields to be flooded. The Texas Permian Basin, North Dakota, the Texas Gulf Coast, and the California area have had CO_2 injection projects in operation for several years.

Because CO_2 is an acid gas, production problems are encountered when CO_2 is injected. Carbon dioxide ionizes in water to form carbonic acid and will react directly with carbon steel. The corrosion rates can be quite high, and pumps can fail in a matter of days after breakthrough of the CO_2 into producing wells. Some scaling problems may arise because carbonic acid may dissolve calcium carbonate from the formation. The calcium bicarbonate formed during this reaction may come out of solution in heaters and vessels as calcium carbonate when CO_2 is lost. Calcium sulfate ($CaSO_4$) will also dissolve and may cause scaling in surface equipment.

Emulsion treating characteristics may change when CO_2 dissolves in oil. Asphaltenes may cause problems by dissolving in CO_2 as it sweeps through the formation and then coming out of solution on the surface.

Elastomers must be selected with care, because they may swell or lose strength when exposed to CO_2. Leaking packers due to seal failure will cause pressure on the annuals of CO_2 injection wells and annular space corrosion.

Carbon Dioxide Production Facilities

Carbon dioxide source wells may produce from a few percent to almost pure CO_2. They may produce both liquid and vapor phase CO_2. The presence of water in the produced CO_2 will cause hydrate formation and corrosion. Hydrate formation can be controlled by glycol dehydration, but special measures must be taken to control corrosion.

A corrosion inhibitor can be added to the producing well to control corrosion. Continuous injection downhole of a water-soluble filming amine inhibitor should protect the tubing and wellhead. The use of type 316L and 304L stainless steels and FRP for completions and flow lines is an alternative to inhibitor use.

In a typical CO_2 production facility, the gas travels through a wellstream heater to a contactor in which water is removed. It is then scrubbed, compressed, and sent to the pipeline. Materials selection in the design of the system is the key to corrosion control in the processing plant. Corrosion-resistant alloys can be used in areas of high corrosion, and carbon steel is used where conditions allow its use. A maximum water content of 60% of saturation is obtained by dehydration so that corrosion of the pipeline is prevented. Dehydration also prevents hydrate formation when temperatures are low.

Injection systems

Water and CO_2 are injected alternately in some systems, such as the SACROC unit in the Kelly Snyder field in west Texas. This is known as the water and gas process.

The distribution system consists of parallel separate lines for water and CO_2 that are carbon steel coated externally and cathodically protected. Carbon dioxide in the line contains less than 50 ppm water, so internal corrosion is minimal. Valves in the system range from bare carbon steel to plastic coated with type 316 stainless steel trim. Fluorocarbon and nylon O-rings have performed satisfactorily, and Buna N rubber is used for stem sealing, although these materials swell somewhat.

Water lines are cement lined with sulfate-resistant cements and artificial pozzolans, as specified in API RP-10E. Most leaks have been due to the failure of asbestos gaskets. The use of grout instead of gaskets has been effective. Water-soluble inhibitors are added to protect voids in cement linings and plastic coatings.

Carbon dioxide injection systems have suffered corrosion problems when the mixing of water and CO_2 at each cycle of alternate CO_2/water injection occurs. Plastic coating and type 316 stainless steel trim, ceramic gate valves with electroless nickel-coated bodies, and electroless nickel-coated check valves were tried. The type 316 stainless steel and ceramic gates performed well, but the other methods failed.

Injection wells originally used type 410 stainless steel wellheads and valves. Severe pitting occurred under deposits laid down from suspended solids in the injection water.

The type 410 stainless steel was plastic coated, and the gates and seats were changed to type 316 stainless steel to correct the problem.

Failures occurred in the couplings of the plastic-coated tubing in the injection wells when the seal rings failed. This was corrected by changing the coating on the couplings from an epoxy-modified phenolic to a polyphenylene sulfide.

Production Systems

Most failures in the SACROC unit were due to rod breakage. Inhibitor programs were satisfactory in some wells, but many did not respond. Plastic-coated rods and spray metal coating with type 316 stainless steel helped to alleviate the problem. The use of fiberglass rods in the upper 70% of the string, along with stainless steel coated rods on bottom, reduced rod breakage to an average of 1.1 per well per year.

Tubing leaks can be controlled with coatings and the use of 9Cr-1Mo and 13%Cr steel tubing where inhibitors fail to control. Flow line corrosion can be controlled by the use of fiberglass-epoxy lines. Other system have experienced problems similar to those found in the SACROC unit and have successfully controlled corrosion with the previously described methods. Inhibitor selection by field testing with linear polarization techniques has resulted in improved protection of producing wells. The linear polarization technique is also used in routine monitoring, along with coupons, iron counts, and caliper surveys.

Corrosion of Oil and Gas Offshore Production Platforms

Offshore structures have been in service in various parts of the world for over 40 years. Early experience was in the Gulf of Mexico with water depths of less than 90 m (300 ft). Technology has advanced to the point at which the largest drilling and production platform stands in more than 305 m (1000 ft) of water.

A platform consists of three parts. The jacket is a welded tubular space frame that is designed as a template for pile driving and as lateral bracing for the piles. The piles anchor the platform permanently to the sea floor and carry both vertical and lateral loads. The superstructure is mounted on top of the jacket and consists of the deck and trusses necessary to support operational and other loads. Generally, platforms are carried from the fabrication yard to the site on a barge and are either lifted of launched off the barge into the water. After positioning the jacket, the main piles are driven through the legs of the jacket, one through each leg. Other piles, known as skirt piles, can be driven around the perimeter of the jacket as needed.

Current design and fabrication practices related to fixed steel offshore structures can be found in industry publications, professional journals, and the proceedings of technical conferences. The most basic American document on this subject is API RP-2A (Ref 62), which was first issued in October 1969 and has had many subsequent editions. Because American experience has been mainly in the Gulf of Mexico, API RP-2A generally represents that experience.

General Corrosion

Marine structures operate in a complex environment that can vary significantly according to site location and water depth. Figure 16 shows the four main platform corrosion zones: soil, seawater, splash zone, and marine atmospheric.

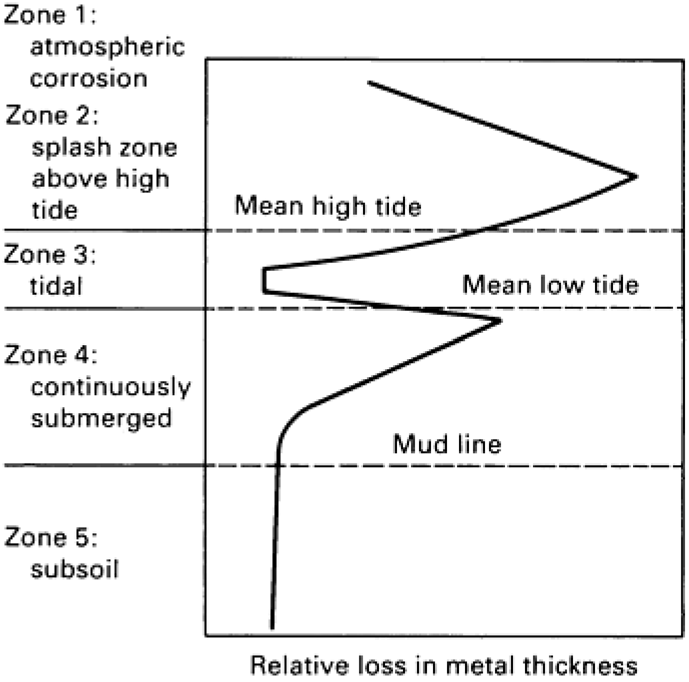

Fig. 16 Corrosion zones on fixed offshore structures. Source: Ref 63

Marine atmospheric corrosion problems occur on the portion of the jacket above the splash zone and on the superstructure. Exposed steel surfaces suffer corrosion from an environment of water condensation, rain, salt precipitation, sea mist, and oxygen. Corrosion rates can range from 0.05 to 0.64 mm/yr (2 to 25 mils/yr). Corrosion is particularly severe at crevices and sharp-edged areas, such as skip-welded plates and steel structural shapes. Attention to design and fabrication details can eliminate most of these problem areas. Atmospheric corrosion can be minimized by using coatings or by substituting nonferrous materials, such as copper alloys, nickel alloys, and FRP for steel components. Care must be taken not to create a galvanic-corrosion problem by coupling dissimilar metals. Table 4 gives a summary description of several marine zones and the characteristic behavior of the steel.

Table 4 Classification of typical marine environments

Marine zone	Description of environment	Characteristic corrosion behavior of steel
Atmosphere (above splash)	Minute particles of sea salt are carried by wind. Corrosivity varies with height above water, wind velocity and direction, dew cycle, rainfall, temperature, solar radiation, dust, season, and pollution. Even bird droppings are a factor.	Sheltered surfaces may deteriorate more rapidly than those boldly exposed. Top surfaces may be washed free of salt by rain. Coral dust combined with salt seems to be particularly corrosive to steel equipment. Corrosion usually decreases rapidlyas one goes inland.
Splash	Wet, well-aerated surface; no fouling	Most aggressive zone for many metals, for example, steel. Protective coatings are more difficult to maintain than in other zones.
Tidal	Marine fouling is apt to be present to high watermark. Oil coating from polluted harbor water may be present. Usually, ample oxygen is available.	Steel at the tidal zone may act cathodically (well aerated) and receive some protection from the corrosion just below tidal zone in the case of a continuous steel pile. Isolated steel panels show relatively high attack in the tidal zone. Oil coating on surface may reduce attack.
Shallow water (near surface and near shore)	Seawater usually is saturated with oxygen. Pollution, sediment, fouling, velocity, and so on, all may play an active role.	Corrosion may be more rapid than in marine atmosphere. A calcareous scale forms at cathodic areas. Protective coatings and/or cathodic protection can be used for corrosion control. In most waters, a layer of hard shell and other biofouling restricts the available oxygen at the surface and thus reduces corrosion (increased stress on structure from the weight of fouling must be provided for).

Continental-shelf depths	No plant fouling, much less animal (shell) fouling with distance from shore. Some decrease in oxygen, especially in the Pacific, and lower temperature	. . .
Deep ocean	Oxygen varies, tending to be much lower than at the surface in the Pacific but not too different in the Atlantic. Temperature near 0 °C (32 °F). Velocity low; pH lower than at surface.	Steel corrosion is often lower. Anode consumption is greater to polarize the same area of steel as at the surface. There is less tendency for protective mineral scale formation.
Mud	Bacteria are often present, for example, sulfate-reducing types. Bottom sediments vary in origin, characteristics, and behavior.	Mud is usually corrosive, occasionally inert. Mud-to-bottom water corrosion cells seem possible. Partly embedded panels tend to be rapidly attacked in mud. Sulfides are a factor. Less current than in seawater is consumed to obtain cathodic polarization for the buried part of the structure.

Source: Ref 64

The splash zone is defined in NACE RP-01-76 (Ref 65) to be the area of the platform that is alternately in and out of the water because of tides, winds, and sea. It does not include surfaces that are only wetted during major storms. The splash zone of the platform can cover in interval of 1.5 to more than 12 m (5 to more than 40 ft), depending on location. Generally, the area of the platform that suffers the most severe steel corrosion is the splash zone, as shown in Fig. 17. Common methods of controlling corrosion in the splash zone include applying coatings, increasing jacket wall thickness by 6.4 to 19 mm (0.25 to 0.75 in.) in the splash zone to compensate for the higher corrosion rates, or applying a Monel alloy wrapper.

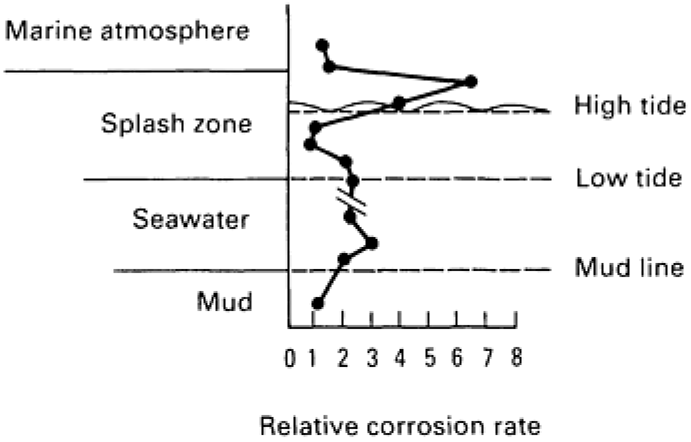

Fig. 17 Zones of corrosion for steel in seawater and the relative corrosion rate in each zone. Source: Ref 65

Corrosion of steel in seawater is a function of water salinity, temperature, oxygen content, velocity, resistivity, and chemistry. Table 5 summarizes the effects of these and other factors on the corrosion of steel in seawater. Several of the variables controlling corrosion are interrelated. As an example, Table 6 demonstrate the relationship between temperature and oxygen solubility in seawater. The lower the temperature, the higher the solubility. As temperature or oxygen levels increase, corrosion rates will increase. To control seawater corrosion, the steel jackets are normally cathodically protected. The types of cathodic protection systems used are sacrificial anode, impressed current, or a combination of the two (see the discussion "Cathodic Protection" in this article). Occasionally, cathodic protection will be used in combination with coatings. Not only does cathodic protection control corrosion but it also eliminates concern over a corrosion fatigue failure of the jacket. Corrosion fatigue is discussed in more detail below. Typical cathodic protection system design parameters are given in Tables 7 8 9.

Table 5 Factors that affect corrosion of carbon steel immersed in seawater

Factor	Effect on iron and steel
Chloride ion	Highly corrosive to ferrous metals. Carbon steel and common ferrous metals cannot be passivated. Sea salt is about 55% chloride.
Electrical conductivity	High conductivity makes it possible for anodes and cathodes to operate over long distances; therefore, corrosion possibilities are increase, and the total attack may be much greater than that for the same structure in freshwater.
Oxygen	Steel corrosion is cathodically controlled for the most part. Oxygen, by depolarizing the cathode, facilitates the attack; therefore, a high oxygen content increases corrosivity.
Velocity	Corrosion rate is increased, especially in turbulent flow. Moving seawater may destroy the rust barrier and provide more oxygen. Impingement attack tends to promote rapid penetration. Cavitation damage exposes fresh steel surfaces to further corrosion.
Temperature	Increase ambient temperature tends to accelerate attack. Heated seawater may deposit protective scale or lose its oxygen; either or both actions tend to reduce attack.
Biofouling	Hard-shell animal fouling tends to reduce attack by restricting access of oxygen. Bacteria can take part in the corrosion reaction in some cases.
Stress	Cyclic stress sometimes accelerates failure of a corroding steel member. Tensile stresses near yield also promote failure in special situations.
Pollution	Sulfides, which are normally present in polluted seawater, greatly accelerate attack on steel. However, the low oxygen content of polluted water could favor reduced corrosion.
Silt and suspended sediment	Erosion of the steel surface by suspended matter in the flowing seawater greatly increases the tendency toward corrosion.
Film formation	A coating of rust or rust and mineral scale (calcium and magnesium salts) will interfere with the diffusion of oxygen to the cathode surface, thus slowing the attack.

Table 7 Design criteria for offshore cathodic protection systems

Production area	Water resistivity, Ω·cm[a]	Environmental factors[b]			Lateral water flow	Typical design current density[c]	
		Water temperature		**Turbulence factor (wave action)**			
		°C	**°F**			**mA/m²**	**mA/ft²**
Gulf of Mexico	20	22	70	Moderate	Moderate	54-65	5-6
U.S. West Coast	24	15	60	Moderate	Moderate	76-106	7-10
Cook Inlet	50	1	35	Low	High	380-430	35-40
North Sea[d]	26-33	0-12	32-55	High	Moderate	86-216	8-20
Persian Gulf	15	30	85	Moderate	Low	54-86	5-6
Indonesia	19	24	75	Moderate	Moderate	54-65	5-6

Source: Ref 65

(a) Water resistivity is a function of chlorinity and temperature, and it decreases as both chlorinity and temperature increase.

(b) Typical values and ratings based on average conditions, remote from river discharge.

(c) In ordinary seawater, a current density less than the design value will suffice to hold the platform at protective potential once polarization has been accomplished and calcareous coatings are built up by the design current density. It should be noted, however that depolarization can result from storm action.

(d) Conditions in the North Sea can vary greatly from the northern to the southern area, from winter to summer, and during storm periods.

Table 8 Energy capabilities and consumption rates of sacrificial anode materials in seawater

Anode material	Energy capability[(a)]		Consumption rate		Anode to water[(b)] closed circuit potential, V versus Ag/AgCl reference electrode
	A·h/kg	**A·h/lb**	**kg/A·yr**	**lb/A·yr**	
Aluminum-zinc-mercury	2750-2840	1250-1290	3.1-3.2	6.8-7	-1 to -1.05
Aluminum-zinc-indium	2290-2600	1040-1180	3.4-3.8	7.4-8.4	-1.05 to -1.1
Aluminum-zinc-tin	925-2600	420-1180	7.4-20.8	16.3-45.9	-1 to -1.05
High-purity zinc	780-815	354-370	10.7-11.2	24.8-23.7	-1 to -1.05
Magnesium alloy H-1	1100	500	8.0	17.5	-1.4 to -1.6

Source: Ref 65

(a) Data are ranges taken from field tests conducted by the Naval Research Laboratory at Key West, FL and from manufacturers' long-term field tests.

(b) Measured potentials can vary because of temperature and salinity differences.

Table 9 Consumption rates of impressed-current anode materials

Material	Typical anode current density in saltwater service		Nominal consumption rate	
	A/m^2	**A/ft^2**	**g/A·yr**	**lb/A·yr**
Pb-6Sb-1Ag	160-220	15-20	15-86	0.03-0.02[(a)]
Pb-6Sb-2Ag	160-220	15-20	13-25	0.03-0.06[(a)]
Platinum (on titanium, niobium, or tantalum substrate)	540-3200	50-300	3.6-7.3	0.008-0.016[(b)]
Graphite	10-40	1-4	230-450	0.5-1.0
Fe-14.5Si-4.5Cr	10-40	1-4	230-450	0.5-1.0

(a) Very high consumption rates of lead-silver anodes have been experienced at depths in excess of 30 m (100 ft).

(b) This figure can increase when current density is extremely high and/or in waters of low salinity.

The major platform components below the mudline are the jacket piles. In general, steel corrosion rates are low below the mudline. The exception is when the mud contains sulfate-reducing bacteria. Because the piles have electrical continuity with the jacket, the cathodic protection system will normally protect the piles from corrosion in saline muds.

Fatigue

Corrosion is of particular concern for the platform tubular welded joints, called nodes. The nodes are areas of high stress due to their complex geometries (Ref 67, 68, 69). The points of maximum stress in the nodes occur at the toe of the welds joining the tubular members. Cyclic stresses result from environmental factors, such as waves, tides, and operating loads. Platforms are designed to handle both a maximum stress and fatigue. The maximum stress is usually based on 100-year storm conditions. Platform fatigue life is based on a environmental stress distribution analysis, along with analysis of the stress cycles (Ref 70). Fatigue design curves have been published by the American Welding Society. British Standards Institute, American Petroleum Institute, and Det Norske Veritas.

Corrosion can reduce the fatigue life of platform anodes. Galvanic corrosion of nonstress-relieved welds and pitting corrosion can result in stress raisers. Therefore, corrosion can lead to the initiation of cracks and can increase the growth rate of existing cracks, reducing fatigue life. The fatigue life of steel exposed to seawater is shorter than that of steel exposed to air because of corrosion fatigue. As Fig. 18 illustrates, steel immersed in seawater does not exhibit an endurance limit. Because there is no endurance limit, unprotected steel exposed to seawater is susceptible to fatigue failure even at low stress levels after long-term cyclic service. An API study discussed crack initiation in smooth, notched, and welded specimens and summarized a number of earlier investigations (Ref 72). Table 10 ranks according to

importance the various seawater environmental variables influencing corrosion fatigue crack initiation of carbon steel. The corrosion fatigue effects are eliminated by the application of cathodic protection (Fig. 19).

Table 10 Summary of major variables influencing the corrosion fatigue crack initiation behavior of carbon steels in seawater

Variable	Effect
Cyclic frequency	Slower frequencies cause reduced fatigue resistance for unprotected steel.
Cathodic potential	Adequate cathodic protection restores fatigue resistance to levels observed in air.
Oxygen level	Fatigue resistance in deaerated seawater is similar to that in air.
Temperature	Although decreasing temperature results in increased oxygen levels, the overall effect of decreasing temperature is that fatigue resistance is improved to some extent in range of 13 to 45 °C (55 to 115 °F).
pH level	Over a broad range of values (4 to 10), there is little effect of pH on fatigue resistance. Low values (<4) decrease fatigue resistance, and high values (>10) improve fatigue resistance to levels similar to those observed in air.

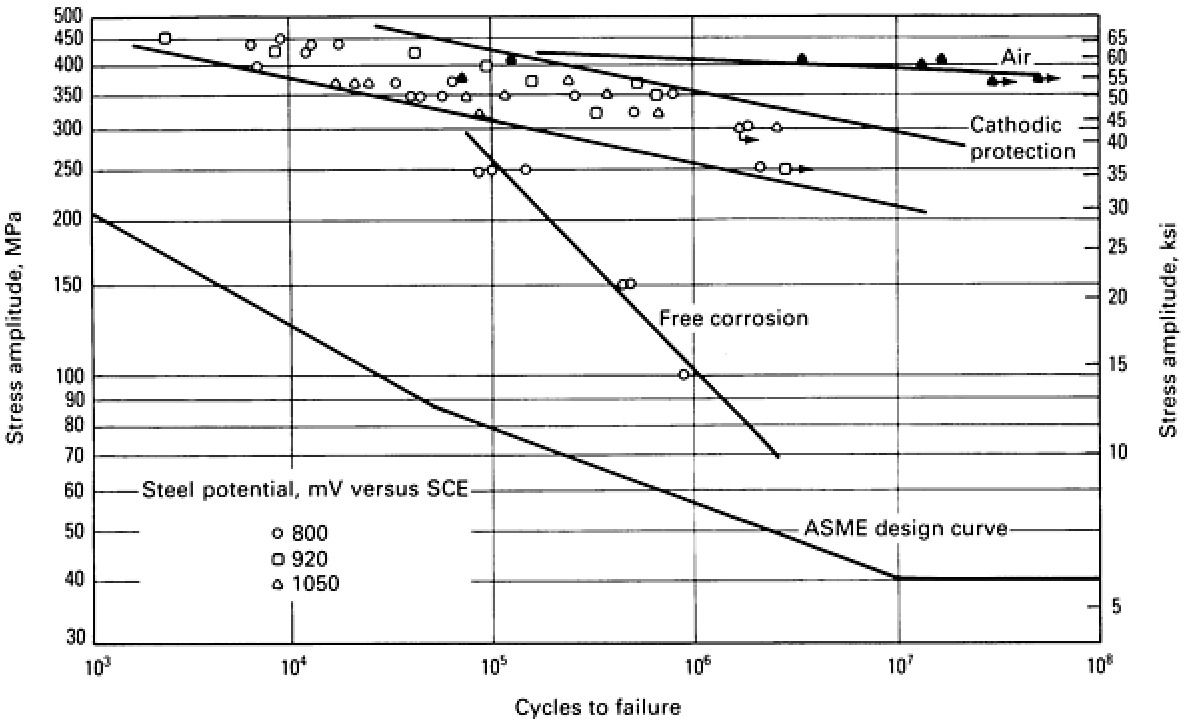

Fig. 19 Effect of cathodic protection on the fatigue performance of alloy steel in seawater. Tests performed on 6.4-mm ($\frac{1}{4}$-in.) diam specimens at a mean stress of 425 MPa (69 ksi).

Inspection

The purpose of periodic inspection is to ensure that the structure is fit for continued service. Through the inspection program, a company is protecting its personnel and assets. In some locations of the world, governmental bodies have established legislation or code agencies that determine minimum inspection requirements. Elsewhere, the operator decides on the minimum inspection needs for the platform.

Inspection is required even though platforms are design and constructed to conservative codes (Ref 73). Inspection allows confirmation that the codes are adequate. It should be noted that the codes represent the best experience and knowledge at the time they are written. Often, the design parameters must be extrapolated for use in new frontier environments that were not foreseen when the codes were written. Inspection results provide the information necessary for updating the codes to account for these new environments. Inspection of the platform jacket is designed to assess corrosion, fatigue cracks, joint and brace failure, impact damage, marine growth, scour, and debris accumulation. Inspection techniques include visual inspection by divers and remote operated vehicles, still and video photography ultrasonic thickness measurements, cathodic potential surveys, magnetic-particle inspection, and vibration frequency attenuation.

Corrosion of Gathering Systems, Tanks, and Pipelines

Gathering systems are defined as all production facilities from the wellhead choke (or pumping T) to the sales point (oil and/or gas); subsystems include flow lines, separation, and dehydration. Gas processing will be reviewed briefly. Sulfur plants (conversion of H_2S to elemental sulfur), gas transmission lines and oil pipelines, gasoline plants, and water-handling facilities for disposal are beyond the scope of this discussion, although the same principles will apply. Internal and external corrosion alleviation systems will be reviewed, respectively.

Internal corrosion is dependent on the composition, temperature, pressure, and flow regime of the produced fluids. Although the general direction of the effect of each of these items is known, the magnitude of the effect is not precisely known, and the interrelationship of all these effects is not well understood. In short, corrosion alleviation is not an exact science (Ref 74).

A natural gas reservoir is a reservoir that, under initial conditions, is a single, gaseous hydrocarbon phase. If this gaseous phase contains hydrocarbons that are recoverable as liquids on the surface, the reservoir is a gas condensate reservoir. A gas well is a well that produces fluids from a gas or gas condensate reservoir. An oil well is a well that produces from a hydrocarbon reservoir that is either a two-phase system or a single liquid phase (Ref 75). Because produced fluids essentially determine the internal environment (weather conditions and process design can affect temperatures and pressures), gathering systems for gas wells and oil wells will be discussed separately.

From both a metallurgical and corrosion viewpoint, it is important to distinguish between sweet gas wells and sour gas wells. If the partial pressure of H_2S is greater than 0.34 kPa (0.05 psia), the gas stream is sour and materials that resist sulfide stress cracking must be used. The latest revision of NACE MR-01-75 list materials that are recognized to have acceptable resistance to sulfide stress cracking.

The determination of whether H_2S or CO_2 corrosion mechanisms will predominate is not as simple. Early investigators believed that CO_2 had a synergistic effect on H_2S corrosion. Subsequent investigators indicate that it is the ratio of partial pressures of CO_2 to H_2S that controls the corrosion mechanism. According to studies by one researcher, unless the ratio of CO_2 to H_2S partial pressure is greater than 500, the corrosion mechanism is dominated by H_2S (Ref 76). More recent investigations suggest that at some temperatures when the ratio of CO_2 to H_2S partial pressure is plotted versus corrosion, there is a sharp discontinuity as the ratio is reduced when the controlling mechanism changes from CO_2 to H_2S, but not always at 500. At other temperatures, the data suggest that the change in corrosion mechanism from CO_2 to H_2S controlled as the ratio of partial pressure of CO_2 to H_2S is reduced is a continuous function, rather than the above step function (Ref 77).

Because CO_2 corrosion is usually more severe than H_2S corrosion at cool conditions and because most production facilities are relatively cool, CO_2 corrosion should be considered whenever the ratios of CO_2 to H_2S partial pressures are greater than 100. Oxygen is never present naturally in oil and gas reservoirs, and without exception, it is preferable to keep it out rather than to alleviate its corrosion effects.

Sweet Gas

With regard to CO_2 corrosion alleviation in flow lines, there are several choices. First, low-alloy steel with a corrosion allowance can be used; a nomograph establishes the maximum corrosion rate for CO_2 (Ref 78). Velocity may also be important; several authors have suggested that there is a critical velocity above which CO_2 corrosion is very difficult to control (Ref 79). Again, more recent data suggest that at the same temperature, pressure, composition, and pH, the CO_2 corrosion-velocity relationship is a continuous relationship rather than a step function (Ref 77). If the flow lines are welded, the operator should be certain that the weldments are at least as corrosion resistant (and where H_2S is present, as cracking resistant) as the pipe body.

A second choice is to use corrosion-resistant materials, alloys, or coatings. With regard to CO_2, either type 316 stainless steel or duplex stainless steel will provide sufficient internal corrosion resistance. If H_2S is present, then NACE MR-01-75 must be followed. Type 316 stainless steel is subject to chloride SCC at elevated temperatures, and both alloys (type 316 stainless steel and duplex) may be subject to external pitting corrosion or crevice corrosion. Both alloys also require special care from the time they are installed to the time they are put into service. Oxygen and perhaps bacteria will result in pitting corrosion. Metallurgical solutions, if properly executed, result in permanent low-maintenance corrosion alleviation systems.

A third choice is to internally line low-alloy steel pipelines with a corrosion-resistant material. These systems may have advantages over solid corrosion-resistant alloys. First, they may be less expensive, and second, the alleviation of external corrosion problems of low-alloy steel is well understood (years of history with large quantities of pipelines) and less sophisticated. There are two disadvantages. Special welding procedures are required, and when the metallurgical coating is not bonded, buckling of the liner may occur, particularly in bends. This buckling will inhibit the use of tools pumped through the flow line.

Two other internal coatings are also commonly used: organic polymers (plastic coatings) and cement linings. Both systems can be economic successes. However, both systems have difficulty in maintaining corrosion resistance at the joints, are difficult to install holiday-free, have limited life, and may suffer disbondment and failure when the pipe is improperly handled or distorted. The plastic coatings are permeable to the produced fluids, and eventually (3 to 5 years), the corrosive fluids will permeate the coating. The resulting corrosion products cause disbonding of the coating and

complete loss of its corrosion resistance. Cement linings are thicker and less subject to produced fluid penetration than plastic coatings. They are heavy and may have limited resistance to acids.

A final alternative is to use nonmetallic pipe materials such as FRP or polymerized hydrocarbons. The advantage of these materials is their complete resistance to corrosion. Their disadvantages are low allowable temperatures, low fatigue resistance, low strength, low resistance to mechanical damage, and high combustibility. They also have problems with joint integrity. Finally, they may be vulnerable to attack from the produced fluids (CO_2 may dissolve the resins from fiberglass pipe, and unsaturated hydrocarbons may dissolve the polymerized hydrocarbon pipes).

An alternative to corrosion-resistant materials is to use corrosion inhibition. If corrosion inhibition is used to protect the gas well downhole tubulars, the same system will protect the flow lines if the flow lines are properly designed. The flow lines should be sized to ensure turbulent flow at a velocity that is not significantly higher than that present in the tubing. Turbulent flow will ensure inhibitor contact with the entire internal pipe surface, and limited velocities (flow lines are cooler than gas well tubulars) will ensure that flow line conditions are not significantly more corrosive than the gas well tubulars. Because the economic consequences of downhole tubular failures, are usually much greater than flow line failures, designing the surface flow lines to utilize downhole inhibition systems effectively will result in a successful flow line inhibition system. If downhole inhibition system is not used, then surface inhibition can be used to protect the flow lines. In low velocity/low liquid flow regimes, periodic inhibition with a technique that inhibits the entire internal surface can be successful. For higher velocities (turbulent flow) and/or high liquid content, continuous inhibition will probably be necessary.

Separation and dehydration facilities offer fewer alternatives. Because inhibitors usually stay in the liquid phase in multiphase systems and usually in the hydrocarbon phase if one is present, reliable inhibition of the vapor space is impossible. Fortunately, corrosion is usually not severe, because only water of condensation is present. For very severely corrosive environments, such as wet CO_2, type 316 stainless steel or type 316 stainless steel internal cladding is usually used. For normal gas production with CO_2, low-alloy steel, combined with a corrosion allowance and monitoring, is used.

For gas dehydration systems, low-alloy steel with corrosion allowance is normally sufficient when combined with pH control of the glycol. For gas streams high in CO_2 concentrations, some operators have found it necessary to internally clad the wet gas portions with type 316 stainless steel.

Sour Gas

Sour gas wells present a more difficult problem. First, all materials must be resistant to sulfide stress cracking. It is essential that no equipment suffer catastrophic cracking failures. General corrosion is less severe for H_2S than for CO_2 at the lower temperatures usually encountered in flow line systems, and H_2S corrosion is not velocity dependent. As long as sufficient liquid hydrocarbon is present, corrosion is usually minor. When hydrocarbon liquids exceeds 100 barrels per 28,300 m^3 (1,000,000 ft^3) of gas, when the water content of the liquid phase is less than 10%, and when the flow is turbulent (to avoidwater phase in the bottom of the line), no serious corrosion problem should be expected. In cases in which the above conservative criteria are not met, inhibition may be necessary. The same rationale in regard to the use of inhibitors in flow line with CO_2 applies to flow lines for H_2S. Inhibition systems that protect downhole tubulars will protect the flow lines if the entire internal wall is inhibited. Processing facilities, gas separators, and sweeting systems (sulfinol, amines, and so on) are usually constructed of low-alloy steel with a corrosion allowance and are regularly monitored.

Oil Wells

Oil wells, as previously defined, are wells that produce from a hydrocarbon reservoir that is either two-phase or a single liquid phase. Oil well flow line corrosion is much easier to handle than gas well flow line corrosion. First, sour oil wells are usually beyond the scope of NACE MR-01-75. Second, CO_2 corrosion is seldom, if ever, a problem. Most crude oils (and associated gas) either contain no CO_2 or sufficient H_2S for H_2S to be the controlling corrosion mechanism. Corrosion problems are often minor until water-cuts approach 30%. Normally, when water-cuts are high enough for saltwater (with or without H_2S) corrosion to be a problem in the flow lines, corrosion will be more severe on the downhole tubulars, and the inhibition system protecting the tubulars will protect the flow lines. Flow lines with stratified flow that allow free water to flow or stagnate in the bottom of the flow lines may suffer corrosion problems. In these cases, inhibitors in the oil phase from the well may not help. This problem is successfully handle by frequent pigging in order to clear the flow lines of water; to clean out sediment, which will foster crevice corrosion; and to distribute inhibitor over the entire internal surface.

Gas separation facilities and free water knock outs are usually made of low-alloy steel. Free water knock outs are often internally coated with an organic coating. Coatings, if properly applied to clean dry surfaces, may extend the vessel life a few years. Generally, coating do not remain holiday-free for very long in saltwater service. The only other alternative to low-alloy steel with corrosion allowance and internal coating is a corrosion-resistant material. The low corrosivity, however, does not justify the cost of a corrosion-resistant alloy, either solid or internally clad. The combination of size and pressure usually eliminates the use of materials such as fiberglass.

Corrosion problems can be severe in saltwater-handling facilities, although they are usually mild to moderate. Corrosion alleviation systems are limited to cathodic protection, organic coatings, and, occasionally, nonmetallic vessels.

Crude oil is usually dehydrated by using gravity separation of the lighter oil from the unwanted water. Heat, chemicals, and electric fields are often used to accelerate the gravity separation. The separation vessel should not experience severe corrosion if the system is kept oxygen-free. Cathodic protection is only partially successful for the vessel, because only the water-wet portion is protected and the oil/water interface fluctuates. The heating coils often suffer more severe corrosion than the vessel body. As long as these coils are in the water portion of the vessel, well designed and maintained cathodic protection systems are successful in alleviating corrosion of the heating surfaces. When large tanks are used, galvanizing significantly prolongs the tank life in the absence of H_2S. Hot-dip galvanizing is considered to be the most effective treatment, but it is limited to bolted tanks. The bolted tank gaskets, in turn, limit the temperatures at which the vessel can be operated.

The gas separated from the oil is low pressure and can be safely handled with low-alloy steel with a corrosion allowance. The storage of dehydrated oil (usually about 1% H_2O) poses no internal corrosion problems, except in the tank bottom, where salt water will accumulate.

External Corrosion

External corrosion can also be a serious and costly problem. In wet or corrosive soil, low-alloy steel flow lines should be coated. There are a variety of successful coating systems. Usually, the external coating system consists of two parts: a mastic that coats and protects the pipe and a coating or wrapping that protects the mastic. If the flow lines are needed for long periods of time, then the external coating should be supplemented with cathodic protection. Surprisingly, it is probably more important to cathodically protect corrosion-resistant alloy flow lines than low-alloy steel flow lines. The corrosion-resistant alloys--type 316 stainless steel or duplex stainless steel--are subject to crevice corrosion in the presence of oxygen. Because the stainless steel lines are much more expensive than low-alloy steel lines, they cannot be allowed to fail by external corrosion. Therefore, external cathodic protection of these flow lines is essential when they are buried or submerged. To reduce the current level required for protection, the corrosion-resistant alloy, like the low-alloy steel pipeline, is usually externally coated.

The other components of the gathering system are the storage tanks, gun barrels, and surge tanks. As has been reviewed earlier, these vessels all internally accumulate salt water on the bottom. Similarly, these tank bottoms are all subject to external corrosion. Because the tank bottoms are relatively thin and may suffer internal corrosion, they should be protected from external corrosion. Therefore, in wet environments or where long service is needed, cathodic protection of tank bottoms should be considered. For piping and vessels above ground, painting is the accepted method of protecting against corrosion.

Monitoring

Monitoring is an essential part of any corrosion alleviation system. No corrosion alleviation system is completely reliable, and in many cases failure can be catastrophic, both from a personal safety perspective and from an environmental and/or economic perspective. There are a wide variety of inspection techniques. The thoroughness and frequency of the monitoring must be weighed against the consequences of failure, and the type of monitoring must be tailored to the particular system. Certainly, it is more catastrophic to have a high-pressure sour gas vessel failure than an atmospheric saltwater tank failure.

Flow lines can be monitored with calipers that are pumped through the line, x-rayed, or, where warranted, cut open and inspected. Vessels can be visually and/or ultrasonically inspected. When ultrasonic inspection is used, reference points are usually permanently fixed to the vessel external wall so that the ultrasonic test is conducted at the same location each time.

Storage of Tubular Goods

Tubular goods used in oil-producing and drilling operations are sometimes stored outdoors or in areas where internal storage is conducive to corrosion. This is particularly true in coastal regions and industrial areas in which acid gases and pollutants are present as well as in oil fields that produce hydrogen sulfide.

Oxygen corrosion, or rust, is aggravated by the deposition of salt from marine environments, such as that encountered in wind-driven spray on offshore platforms, and airborne salt in coastal areas. Pipe yards situated close to the beach are particularly susceptible to severe atmospheric corrosion. In warehouses and under sheds, the presence of industrial pollutants such as SO_2, oxides of nitrogen, and other gases will initiate corrosion attack and increase rusting when they react with moisture in the air or on the pipe.

Even in areas of relatively low salt and pollutants content, severe corrosion may occur if the relative humidity is high. The pipe will cool off during the night, and dew will fall, covering the pipe with a conductive layer of electrolyte. The rust that is already on the pipe is hygroscopic and will remain moist after the free water has evaporated. This leads to concentration cell attack and severe pitting. Pit depth and size are of particular importance, because failures may occur when the pipe is put into service under pressure.

Inspection

Before being put into service, tubular goods that have been stored for any length of time should be inspected. Particular attention should be given to the following areas:

- *External rusting:* The percent of surface area covered by rust should be recorded
- *Presence of mill scale, lacquer-type mill coatings, or other temporary coatings:* This is important, because areas not covered may corrode, while protected areas may set up concentration cells and accelerate localized corrosion
- *Internal corrosion:* The interior of the pipe should be inspected for rusting and pitting
- *Condition of threads:* Threads should be examined to determine if corrosion damage has occurred that could prevent proper makeup

Cleaning

After inspection, the pipe should be cleaned prior to applying any protective coatings. The pipe can be cleaned mechanically or with acids or rust dissolvers.

If the pipe is used, or has been stored in marine or industrial environments, it should be water blasted to remove any salt or acid deposits, weathered for a period of time to allow underdeposit salts to migrate to the surface, and water blasted again. One month is usually sufficient weathering time.

A water-soluble phosphate-base temporary rust inhibitor can be applied during the weathering period to minimize further rusting. The inside of the pipe should also be protected because water may collect on the bottom and cause pitting.

The pipe can now be physically cleaned. Wire brushing with an automated machine is a preferred method, but a rotary hand-held wire brush can be used if a machine is not available. If rusting and pitting are severe, the pipe should be sand blasted. The inside of the pipe can be cleaned with a mechanical rattler or a round brush.

An alternative cleaning method for lightly rusted pipe or where mechanical cleaning facilities are unavailable is the use of an acid-base rust remover/chelant. These are usually based on phosphoric acid and will contain inhibitors and passivators to prevent removal of metal. The pipe can be soaked in a trough of the inhibited acid cleaner until deposits are dissolved.

Application of Protective Coatings

Once the pipe is cleaned, temporary rust-preventive coatings can be applied to halt further rusting. They can be applied by the automatic machine that cleans the pipe or by hand sprayers, dipping, or brushing. The important factor is that the pipe is completely covered with the coating. Temporary coatings are manufactured in several types, as discussed below.

Lacquer coatings may consist of an oil-soluble resin in a volatile hydrocarbon solvent. These coatings may be brittle and may flake off and expose bare metal.

Slushing compounds usually consist of asphalt dissolved in a nonevaporating hydrocarbon so that a thick, oily layer is present on the surface. These compounds are resistant to mechanical damage, but may be difficult to apply and remove.

Polymeric coatings may contain acrylics, chlorinated vinyl chlorides, or other materials that will dry and polymerize from an aqueous solution. The coating is similar to that found when floor was is applied. These coatings may contain metal passivators and rust converters that will be anodic to the metal surface and greatly alleviate further rusting. Polymeric coatings are easy to apply and are sometimes used without precleaning the surface, because the converters and passivators are design to modify corrosion by-products to eliminate concentration cell corrosion.

Sulfonate-base coatings are formulated from petroleum sulfonates, waxes, and materials that form a flexible and nondrying coating. Pigments and fillers can be added for appearance and durability. The sulfonate acts as a rust inhibitor, and the other materials seal the surface to prevent moisture entry. These are relatively easy to apply and are resistant to mechanical damage.

Rust passivators are of the same type as the phosphoric acid base rust removers, or may be similar to the polymeric coatings. They are used for rust prevention under sheds or in warehouses and may not be adequate for outdoor storage in corrosive areas.

The application method used will depend on the type coating selected. A hydrocarbon-base coating can be brushed or sprayed, or the pipe can be dipped in a trough containing the coating. Dilution with naphtha, aromatic solvents, or diesel oil can be done, depending on the recommendations of the manufacturer. A hydrocarbon-base coating should not be applied to wet or damp pipe. Some coatings are reported to be able to displace water from a metal surface, but care should be taken that the surface is not too wet.

A water-base coatings will probably be applied full strength. It can also be sprayed or brushed. The recommendations of the manufacturer should be followed to ensure proper coverage.

A suitable thread-protecting compound should be applied and thread protectors screwed onto the threads before the pipe is coated. It may be desirable to coat the inside of the pipe with an oily coating and to use pipe caps to prevent water entry during storage.

If the coating is air sprayed, the pipe should be coated one layer at a time, making certain that the spray is adjusted to provide coverage without excessive loss. The pipe should be rolled, and the other side covered. The use of wood spacers between the layers of pipe allow any moisture to drain and dry during subsequent outdoor storage. Once the pipe is coated, sufficient drying time should be allowed before the pipe is moved.

Continuing Maintenance

The pipe should be inspected at preselected intervals to ensure that the coating is performing satisfactorily. The program can be modified, or the pipe can be recoated when needed. Complete records should be maintained so that corrosion prevention is an on-going and effective process.

Industry Standards

Donald S. Burns, Spraymetal, Inc.; James W. Johnson, WKM Division of Cooper Industries

This section will discuss the applicable standards for metallic materials used in critical environmental conditions that may cause resistant materials to behave abnormally. Selection of materials for drilling, completion, production, and transportation of oil and gas is covered in several standards. In some cases, one standard may override another that addresses the same product. The following standards will be discussed: NACE MR-01-75, API 6A and 6D, ASME section IX and API 1104 (welding), API 14D, and ANSI standards.

Materials and Design Specifications

NACE MR-01-75 (1978 revision) and all later revisions cover the requirements for metallic materials used in the drilling and completion of oil and gas wells and the production of oil and gas that contain hydrogen sulfide (H_2S). Hydrogen sulfide is highly toxic; concentration as low as 1000 ppm can cause death. The safe use of H_2S is discussed in NACE TM-01-77.

In addition to the necessary safety considerations, oil and gas that contain H_2S can cause materials that are normally strong and ductile to fail in a sudden and brittle manner at very low stress levels. The special metallurgical requirements for metallic materials in this environment are discussed in NACE MR-01-75.

In general, all carbon and low-alloy steels that are properly heat treated to a maximum hardness of 22 HRC are acceptable for use in H_2S service with two exceptions; free-machining steels and steels containing more than 1% Ni. Laboratory tests have indicated that these materials can fail at hardnesses below 22 HRC.

As their hardness exceed 22 HRC, carbon and low-alloy steels become progressively more susceptible to failure. Laboratory tests have indicated almost instantaneous failures at stresses considerably below yield for hard materials; therefore, all carbon and low-alloy steels can be made susceptible to sulfide stress cracking by improper thermal treatment and/or by mechanical damage (cold work) due to handling problems.

In addition to carbon and low-alloy steels, NACE MR-01-75 discusses stainless and other high-alloy steels. Some of these steels can be used at hardness above 22 HRC when additional strength is needed. These materials should be selected with care.

API 6A and 6D present design and material requirements for oil and gas production and pipe-line equipment. The API standards usually contain references to ASTM, AISI, ASME, or other general specifications for acceptable materials for these products and always include a reference to NACE MR-01-75 when the products are to be used in H_2S service. The engineer must be aware that in certain cases the NACE standard may overrule API or other standards and that under these conditions design considerations must be addressed.

Recent concern about consistency in quality and product performance prompted API to rewrite API 6A. The new standard was issued in April 1986, and it requires manufacturers of API equipment to produce and maintain a documented control system that can be audited. This control system must also be capable of providing engineering, manufacturing, and quality guidelines for the consistent production of products meeting the requirements of the revised edition. Before approval, each manufacturer certified will be audited by an independent API-approved auditing team.

The new document also introduces four products specification levels, which can be used to specify the desired quality level. In addition to the quality levels, API has added various environmental conditions. These enable the end user to be very specific in terms of product end use, the expected quality level, and product performance.

ASME section IX and API 1104 discuss the welding of pressure vessels and line pipe, including the requirements for qualifying welding procedure, welders, and the quality level of the production weldments. These standards also identify the variables that dictate when different procedures are required to cover material thickness, material chemistry, joint design, welding position, and thermal treatments. If weldments are to be used in H_2S environments, such factors as additional hardness testing, the type of welding electrode, and the wire/flux combination used should be considered.

The American Petroleum Institute and the National Association of Corrosion Engineers publish documents that indicate whether weldments made with certain wire/flux combinations have experienced failure in H_2S environments under conditions in which failures were unexpected. Weldments with high manganese and silicon contents have been shown to be very susceptible to sulfide stress cracking at hardness at or below 22 HRC even after thermal treatments.

If temperature is an environmental consideration, the designer should be aware that the ability of materials and weldments to withstand sudden impact loading decreases significantly with temperature. Materials and weldments that have ductile characteristics at room temperature (20 °C, or 70 °F) may behave in a brittle manner when exposed to lower temperatures. In addition to the typical mechanical-property testing of materials and weldments, impact testing is required to ensure that the product is properly designed for the anticipated operating temperatures. Standards from ASTM, ASME, and others address these design requirements and generally specify materials that have Charpy V-notch impact test requirements added to the normal mechanical-property tests.

In the case of weldments, Charpy V-notch impact testing of the base metal, the heat-affected zone, and the weld metal is also required to ensure that the weldment will function satisfactorily at the design temperature. Welding must be performed with care to ensure that the completed weldment is produced in accordance with standard procedures.

API 14D establishes requirements for well-head surface safety valves (SSV valves), underwater safety valves (USV valves), and their actuators (SSV/USV actuators). The requirements include design, material quality, performance testing, and functional testing.

Equipment manufactured to this specification is primarily intended for service in outer continental waters (OCS) contiguous to the United States. The equipment is identified with the API 14D monogram. It is also eligible for the OCS monogram when manufactured under a quality program conforming to ANSI/ASME-SPPE-1 specifications. The federal government has mandated that all such equipment installed in federal OCS waters have both monograms.

The ANSI/ASME-SPPE-1 standards establish requirements for quality programs, accreditation of quality programs, and reporting of malfunctions and failures. Manufacturers conforming to these standards are authorized by ASME to apply the OCS monogram to SSVs (valve and actuator).

Corrosion in Petroleum Refining and Petrochemical Operations

J. Gutzeit, Amoco Corporation; R.D. Merrick, Exxon Research and Engineering Company; L.R. Scharfstein, Mobil Research and Development Company

Introduction

CORROSION has always been an unavoidable part of petroleum refining and petrochemical operations. Although certain materials problems are caused by other factors, a predominant number are due to various aspects of corrosion. Corrosion problems increase operating and maintenance costs substantially. Scheduled and unscheduled shutdowns for repairing corrosion damage in piping and equipment can be extremely expensive, and anything that can be safely done to keep a process unit on stream for long periods of time will be of great benefit. A large proportion of corrosion problems are actually caused by shutdowns. When equipment is opened to the atmosphere for inspection and repair, metal surfaces covered with corrosion products will be exposed to air and moisture. This can lead to pitting corrosion and stress-corrosion cracking unless preventive measures are implemented. When equipment is washed with water during a shutdown, corrosion can be caused by pockets of water left to dry.

Most petroleum refining and petrochemical plant operations involve flammable hydrocarbon streams, highly toxic or explosive gases, and strong acids or caustics that are often at elevated temperatures and pressures. Among the many metals and alloys that are available, relatively few can be used for the construction of process equipment and piping (Ref 1). These include carbon steel; some cast irons; certain low-alloy steels and stainless steels; and, to a much lesser degree, aluminum, copper, nickel, titanium, and their alloys. This article will present the considerations and concerns involved in selecting materials for process equipment in refineries and petrochemical plants. In addition, specific information on mechanical properties, corrosion, stress-corrosion cracking (SCC), erosion, and corrosion control will be provided.

Materials Selection

The selection of materials of construction has a significant impact on the operability, economics, and reliability of refining units and petrochemical plants. For this reason, materials selection should be a cooperative effort between the materials engineer and plant operations and maintenance personnel. Reliability can often be equated to predictable materials performance under a wide range of exposure conditions. Ideally, a material should provide some type of warming before it fails; materials that fracture spontaneously and without bulging as a result of brittle fracture or SCC should be avoided. Uniform corrosion of equipment can be readily detected by various inspection techniques. In contrast, isolated pitting is potentially much more serious because leakage can occur at highly localized areas that are difficult to detect. The effect of environment on the mechanical properties of a material can also be significant. Certain exposure conditions can convert a normally ductile material into a very brittle material that may fail without warning. A material must not only be suitable for normal process conditions but must also be able to handle transient conditions encountered during start-up, shutdown, emergencies, or extended standby. It is often during these time periods that equipment suffers serious deterioration or that failure occurs.

Of particular concern is what will happen to equipment during a fire. Unexpected exposure to elevated temperatures can not only affect mechanical properties but can also produce detrimental side effects. Although all possible precautions should be taken to minimize the probability of a fire, the engineer responsible for materials selection must recognize that a fire may occur and that the equipment is expected to retain its integrity in order to avoid fueling the fire. This limits the application of materials with low melting points or those that may become subject to damage by thermal shock when fire-fighting water is applied, particularly in the case of refinery piping and equipment used to handle highly flammable hydrocarbon streams. On the other hand, fire resistance need not be considered for cooling-water or instrument-air systems. Although petrochemical plants may include some processes that involve nonflammable or nonhazardous streams, most equipment must be resistant to fires. Lack of fire resistance rules out the use of plastic components in refineries and petrochemical plants despite their excellent resistance to many types of corrosives. In addition, plastic components tend to be damaged by stream-out during a shutdown; this is required in order to free components of hydrocarbon residues and vapor before inspection or maintenance operations. The final step in the materials selection process is a reliability review of the materials and the corrosion control techniques that were selected. There must be total assurance that a plant will provide reliable service under all conditions, including those that occur during start-ups, shutdowns, downtime, standby, and emergencies.

Principal Materials

Materials selection criteria for a number of ferrous and nonferrous alloys used in petroleum-refining and petrochemical applications are presented in this section. Additional information on selecting the proper metal or alloy is available in the article “Materials Selection for Corrosion Control” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook.*

Carbon and Low-Alloy Steels. Carbon steel is probably used for at least 80% of all components in refineries and petrochemical plants because it is inexpensive, readily available, and easily fabricated. Every effort is made to use carbon steel, even if process changes are required to obtain satisfactory service from carbon steel (Ref 2). For example, process temperatures can be decreased, hydrocarbon streams dried up, or additives injected in order to reduce potential corrosion problems with carbon steel (Ref 3). In refineries, fractionation towers, separator drums, heat-exchanger shells, storage tanks, most piping, and all structures are generally fabricated from carbon steel. Carbon molybdenum steels, primarily the C-0.5 Mo grade, can offer substantial savings over carbon steels at temperatures between 425 and 540 °C (800 and 1000 °F). Because C-0.5 Mo steel has better resistance than carbon steel to high-temperature hydrogen attack, it has been extensively used for reactor vessels, heat-exchanger shells, separator drums, and piping for processes involving hydrogen at temperatures above 260 °C (500 °F). Recently, however, questions have been raised regarding the effect of long-term hydrogen exposure on C-0.5 Mo steel. As a result, low-alloy steels are preferred for new construction.

Low-alloy steels for refinery service are the chromium-molybdenum steels containing less than 10% Cr. These steels have excellent resistance to certain types of high-temperature sulfidic corrosion as well as to high-temperature hydrogen attack. To improve resistance to hydrogen stress cracking, low-alloy steels normally require postweld heat treatment. For refinery reactor vessels, which operate at high temperatures and pressures, 2.25Cr-1Mo steel is widely used. For improved corrosion resistance, these are often overlayed with stainless steel. Other applications for low-alloy steels are furnace tubes, heat-exchangers shells, and piping and separator drums. Additional information is provided in the article "Corrosion of Carbon Steels" and "Corrosion of Alloy Steels" in this Volume.

Stainless steels are extensively used in petrochemical plants because of the highly corrosive nature of the catalysts and solvents that are often used. In refineries, stainless steels have been primarily limited to applications involving high-temperature sulfidic corrosion and other forms of high-temperature attack (Ref 4). Most stainless steels will pit in the presence of chlorides (Ref 5).

Martensitic stainless steels, such as type 410 (S41000), must be postweld heat treated after welding to avoid hydrogen stress cracking problems as a result of exposure to hydrogen sulfide containing environments. Typical applications include pump components, fasteners, valve trim, turbine blades, and tray valves and other tray components in fractionation towers. Low-carbon varieties of type 410 stainless steel (S41008) are preferred for furnace tubes and piping, often in combination with aluminizing. Ferritic stainless steels, such as type 405 (S40500), are not subject to hydrogen stress cracking and are therefore a better choice than type 410 (S41000) stainless steel for vessel linings that are attached by welding (Ref 6). Austenitic stainless steels, such as type 304 (S30400) or type 316 (S31600), have excellent corrosion resistance, but are subject to SCC by chlorides. If sensitized, they are also subject to SCC by polythionic acids (Ref 7, 8). Typical applications include linings and tray components in fractionation towers; piping; heat-exchanger tubes; reactor cladding; tubes and tube hangers in furnaces; various components for compressors, turbines, pumps, and valves; and reboiler tubes. Additional information is available in the article "Corrosion of Stainless Steels" in this Volume.

Cast irons, because of their brittleness and low strength, are normally not used for pressure-retaining components for handling flammable hydrocarbons. The main exceptions are pump and valve components, ejectors, jets, strainers, and fittings in which the high hardness of cast iron reduces the velocity effects of corrosion, such as impingement, erosion, and cavitation. High-silicon cast irons (with 14% Si) are extremely corrosion resistant because of a passive surface layer of silicon oxide that forms during exposure to many chemical environments (except hydrofluoric acid). Typical refinery and petrochemical plant applications include valve and pump components for corrosive service. High-nickel cast irons (with 13 to 36% Ni and up to 6% Cr) have excellent corrosion, wear, and high-temperature resistance because of the relatively high alloy content (Ref 9). Typical uses are valve components, pump components, dampers, diffusers, tray components, and compressor parts. Additional information is provided in the article "Corrosion of Cast Irons" in this Volume.

Copper and aluminum alloys are usually restricted to applications below 260 °C (500 °F) because of strength limitations. Admiralty metal (C44300) tubes have been extensively used in water-cooled condensers and coolers at most refineries, but have often performed poorly in overhead condensers, compressor aftercoolers, and other locations where high concentrations of hydrogen sulfide and ammonia are encountered in aqueous condensate. The usual failure modes are pitting, ammonia SCC, and dezincification. Aluminum alloys, at one time, were proposed for refinery use as a substitute for carbon steel and admiralty metal (C44300) heat-exchanger tubes in cooling-water service (Ref 10, 11, 12). Aluminum tubes were found to be highly resistant to aqueous sulfide corrosion in overhead condensers. Unfortunately, fouling and pitting corrosion on the water side have always been a problem, and except for certain limited applications, most refineries do not use aluminum tubes. The only other major refinery use of aluminum has been in vacuum towers, in which aluminum provides resistance to the naphthenic acid corrosion of tray components. Aluminum is also used, in the form of aluminized coatings, to protect low-alloy steels against high-temperature sulfidic corrosion. Additional information is available in the articles "Corrosion of Copper and Copper Alloys" and "Corrosion of Aluminum and Aluminum Alloys" in this Volume.

Nickel alloys are especially resistant to sulfuric acid, hydrochloric acid, hydrofluoric acid, and caustic solutions, all of which can cause corrosion problems in certain refinery and petrochemical operations (Ref 13). As the nickel content is increased above 30%, austenitic alloys become, for all practical purposes, immune to chloride SCC. Nickel also forms the basis for many high-temperature alloys, but nickel alloys can be attacked and embrittled by sulfur-bearing gases at elevated temperatures. Alloy 400 (N04400) is extensively used as a lining for carbon steel equipment to prevent corrosion by hydrochloric acid and chloride salts (Ref 14). For the same reason, Alloy 400 (N04400) tubes have been used in overhead condensers. Alloy 400 (N04400) is also used against corrosion by hydrofluoric acid. High-nickel alloys, including alloy 625 (N06625) and alloy 825 (N08825), are used to reduce the polythionic acid corrosion of flare-stack tips. Alloy B-2 (N10665) is particularly well suited to handling hydrochloric acid at all concentrations and temperatures (including the boiling point), but is attacked if oxidizing salts are present (Ref 15, 16). Alloy B-2 (N10665), alloy C-4 (N10002), and alloy C-276 (N10276) have excellent resistance to all concentrations of sulfuric acid up to at least 95 °C (200 °F). Although expensive, these alloys are used for specific applications to overcome unusually severe corrosion problems. Additional information is provided in the article "Corrosion of Nickel-Base Alloys" in this Volume.

Titanium is a relative newcomer to the refining industry, but it has been extensively used in certain petrochemical processes. Titanium is not a high-temperature metal; welding and cutting must be done under inert gas atmospheres to prevent embrittlement (Ref 17, 18). From a practical point of view, the use of titanium in refinery and petrochemical plant service is limited to temperatures below 260 °C (500 °F) (Ref 19, 20). If hydrogen is present, temperatures should not exceed 175 °C (350 °F) in order to prevent embrittlement due to hydride formation. Titanium is fully resistant to many process streams. Tubes made from titanium grade 2 (R50400) are extensively used in overhead coolers and condensers on a number of refinery units to prevent corrosion by aqueous chlorides, sulfides, and sulfur dioxide. These tubes can corrode, however, beneath acidic deposits. Titanium tubes are often required when seawater or brackish water is used for cooling. Where underdeposit corrosion of pure titanium is a problem, titanium grade 12 (R53400), alloyed with nickel and molybdenum, should be used. Anodizing and high-temperature air oxidizing of titanium grade 2 (R50400) have been shown to be beneficial from a corrosion point of view (Ref 21). Additional information is provided in the article "Corrosion of Titanium and Titanium Alloys" in this Volume.

Codes and Standard Specifications

Rules for the design, fabrication, and inspection of pressure vessels, piping, and tanks are provided by codes that have been developed by industry and/or regulatory agencies in various countries, as shown by the listing in Table 1. In the United States, the ANSI/ASME Boiler and Pressure Vessel Code, Section VIII, which covers unfired pressure vessels, is used by most industries and fabricators. In most states, it is mandatory that the code be followed, and with the heightened

concern over industrial safety, the number of states that require code compliance is increasing. Therefore, the first step in selecting materials of construction is to know what the code covers and what it does not.

Table 1 Construction codes for refinery process equipment

Country	Issuing organization	Source document(s)
Pressure Vessels		
United States	American Society of Mechanical Engineers American National Standards Institute	Boiler and Pressure Vessel Code, Section VII
Great Britain	British Standards Institution	BS 1515: Fusion Welded Pressure Vessel for use in the Chemical, Petroleum and Allied Industries BS 5500: Unfired Fusion Welded Pressure Vessels
Germany	Arbeitsgemeinschaft Druckbehalter (published by Carl Heymans Verlag KG)	A.D Merkblatter
Italy	Associazione Nazionale per il Controllo della Combustione	ANCC Code
Netherlands	Dienst voor Stoomwezen	Regels Voor Toestellen (Rules for Pressure Vessels)
Sweden	Tryckkarlskomissionen (Swedish Pressure Vessel Commission)	Swedish Pressure Vessel Code
Piping		
United States	American Society of Mechanical Engineers American National Standards Institute	B31.3 Code for Pressure Piping
Great Britain	British Standards Institution	BS 3351: Piping Systems for Petroleum Refineries and Petrochemical Plants
Tanks		
United States	American Petroleum Institute	API 620: Recommended Rules for Design and Construction of Large Welded Low Pressure Storage Tanks API 650: Welded Steel Tanks for Oil Storage
Great Britain	British Standards Institution	BS 2654: Vertical Steel Welded Storage Tanks for the Petroleum Industry

The ANSI/ASME Boiler and Pressure Vessel Code also provides a list of acceptable steels and allowable stress values. The detailed specifications for these steels are provided in Sections II A and II B, which are based on ASTM standard specifications (Table 2). The code also provides the method for calculating the required minimum thickness of various components based on design temperature and pressure. The need for heat treating during fabrication and inspection requirements is also defined based on the alloy selected and the pressure-wall thickness. For welded pressure vessels, Section IX of the code defines the requirements for qualifying the welding process to be used.

(a) These specifications are not approved by either the ANSI/ASME Boiler and Pressure Vessel Code or by the ANSI/ASME Code for Pressure Piping B31.3.

The code does not consider the effect of process environment on the materials selected. The code recognizes that corrosion can and does occur, and it provides rules for including corrosion allowances in the calculation of the required pressure-wall thickness; but suitable values for the corrosion allowance must be specified by the designer. It is also the responsibility of the designer to specify any special heat treatments, hardness limitations, or other details that may be required as a result of environmental factors. Similarly, the designer must determine accurately the full range of likely operating conditions, including upsets, that may be encountered so that the design criteria are met.

Mechanical Properties

Elevated-Temperature Properties. As mentioned in the preceding section, the applicable code will specify the allowable stress that is to be used for a particular steel in the design of a given piece of equipment. This allowable stress is based on the temperature to which the equipment will be exposed. Steels operating under normal plant conditions can be exposed to these temperatures for prolonged periods of time without adverse effects on their allowable strength if there is no corrosion. As working temperatures increase, the mechanical strength of most materials decreases. In actual practice, however, a material is more likely to fail at elevated temperatures by creep (elongation) or stress rupture than from a decrease in tensile or yield strength.

For example, Table 3 shows the short-term, elevated-temperature yield strengths of several carbon and low-alloy steels. As can be seen from the tabulated data, all three steels (carbon steel, C-0.5 Mo steel, and 2.25 Cr-1Mo steel) have satisfactory yield-strength values up to 480 °C (900 °F). These values do not, however, adequately represent the long-term resistance of the steels to creep when stressed at elevated temperatures. Instead, creep resistance values are a more accurate measure of elevated-temperature mechanical strength. Creep resistance values are obtained from creep and stress rupture tests at elevated temperatures over a period of 10,000 h and are usually extrapolated to 100,000 h. Table 4 shows creep resistance values of the three steels discussed above. The deterioration of creep resistance of carbon steel at 480 and 540 °C (900 and 1000 °F) is readily apparent, as is the marked improvement afforded by use of 2.25Cr-1Mo steel. Table 5 lists suggested maximum service temperatures for five different steels and alloys based on creep rupture data. In some applications, such as furnace tubes, code-allowable stresses need not be followed, and equipment may be operated at temperatures and stresses that can lead to creep failure. In order to predict failure with greater accuracy, equipment operating in the creep range should be periodically inspected as the design life is approached.

Table 3 Short-term elevated-temperature yield strengths

Test temperature		Carbon steel, 0.2% yield strength		C-0.5Mo steel, 0.2% yield strength		2.25Cr-1Mo steel, 0.2% yield strength	
°C	**°F**	**MPa**	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**
25	80	248	36.0	276	40.0	272	39.5
150	300	208	30.2	241	34.9	247	35.8
260	500	192	27.8	212	30.7	238	34.5
370	700	175	25.4	190	27.6	234	34.0
480	900	148	21.5	175	25.4	193	28.0

Table 4 Creep resistance extrapolated to 100,000 h

Test temperature		Carbon steel, stress for creep rate of 1%		C-0.5Mo steel, stress for creep rate of 1%		2.25Cr-1Mo steel, stress for creep rate of 1%	
°C	**°F**	**MPa**	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**
425	800	95	13.8	150	21.8	. . .	. . .
480	900	41	6.0	98	14.2	152	22.0
540	1000	18	2.6	43	6.2	55	8.0

Table 5 Suggested maximum temperatures for continuous service based on creep or rupture data

Material	Maximum temperature based on creep rate		Maximum temperature based on rupture	
	°C	°F	°C	°F
Carbon steel	450	850	540	1000
C-0.5 Mo steel	510	950	595	1100
2.25Cr-1Mo steel	540	1000	650	1200
Type 304 stainless steel	595	1100	815	1500

Hardness. The hardness of steels is not considered by the code as a specified property. Whether it is the result of forming or welding operations, hardness has, however, a distinct effect on the suitability of a steel for a particular environment. Although carbon steel normally has low hardness values, cooling from elevated temperatures, such as those encountered during welding, may result in localized hard zones. If hardness values exceed 200 HB, carbon steel may become subject to cracking in aqueous sulfide environments. For this reason, it is often necessary to set a maximum hardness limit for carbon steel used in pressure vessels. In some cases, it is desirable to impose a uniform hardness limitation on all pieces of fabricated equipment because the originally intended service application might be changed at some future date to one in which the component would be exposed to an aqueous sulfide environment. A high hardness value is also indicative of an increase in tensile strength and a corresponding decrease in ductility. Steels with high hardness values can be expected to behave in a brittle manner. Low-alloy steels often require heat treatment after welding to reduce hardness in the weld area and to reduce the stresses associated with welding.

Fatigue Strength. Certain components, such as compressors or pumps, require materials with good fatigue resistance properties. Fatigue resistance also needs to be considered when bolting and piping materials are selected. Fatigue resistance is the ability of a load-carrying component to resist fracture from cycles of repeatedly applied forces, such as vibrational or rotational stresses. One common rule of thumb is to limit the average fatigue stress to approximately one-half the ultimate tensile strength of the material involved. Because fatigue involves crack formation, crack propagation, and residual strength, several mechanical properties are involved in determining fatigue resistance. Obviously, higher strength will help a material resist crack formation and final fracture. Other factors to be considered are the cleanliness of the material and whether it hardens or softens under plastic strain. Clean material with a low inclusion content and fine grains will improve fatigue resistance because inclusions can be a source for crack initiation, while fine grains will assist in allowing the crystallographic planes to slip without cracking.

Low-Temperature Properties. Carbon steel begins to lose its toughness and ductility as service temperatures decrease below ambient. Because most equipment in refineries and petrochemical plants is made of carbon steel, insufficient low-temperature toughness could represent a potentially serious problem. Fortunately, few operations are carried out at low temperatures and most equipment made of carbon steel operates at temperatures ranging from ambient to approximately 425 °C (800 °F). Refinery and petrochemical plant equipment and processes that may require special low-temperature toughness grades of steels include liquified-propane storage, ammonia storage, solvent dewaxing units, and liquified petroleum gas (LPG) processing. It is possible, by specifying certain additional requirements, to obtain carbon steels that are suitable for temperatures as low as -45 °C (-50 °F), depending on thickness. To resist brittle fracture at lowered temperatures, steels should be fully killed, fine grained, normalized, and should have received postweld heat treatment.

Typical American Society for Testing and Materials (ASTM) standard specifications for carbon steels with enhanced ability to perform at low temperatures are given in Table 6. Steels, alloyed with 2 to 9% Ni, and austenitic stainless steels can extend the range of available notch-tough steels to even lower temperatures. The simplest quality control test (although not always adequate) for ensuring proper notch toughness is the Charpy V-notch impact test carried out at the minimum design temperature, or lower. A minimum value of approximately 20.5 J (15 ft · lb) is the usual acceptance criterion. The Charpy test is designed to simulate failure of a pressure vessel, containing a fabrication- or service-induced cracklike defect, by rapid crack propagation (brittle failure) when stressed at low temperatures.

Table 6 ASTM standard specifications for carbon steel with enhanced resistance to brittle fracture at lowered temperatures

Product form	Temperature	
	To -30 °C (-20 °F)	**To -45 °C (-50 °F)**
Plate	A516, normalized (may require impact testing)	A516 normalized, stress relieved and Charpy impact tested
Pipe	A524	A333 grade 1 and grade 6
Tube	A210	A334 grade 1 and grade 6
Forgings	A727 and A350 grade LF1	A350 grade LF2
Fittings	A420 WPL6	A420 WPL6
Castings	A352 grade LCA	A352 grade LCB and grade LCC

Embrittlement Phenomena. There are a number of environmental effects on the mechanical properties of low-alloy steels and stainless steels used for refinery and petrochemical plant construction that need to be considered. In almost all cases, the effect is one of embrittlement due to an increase in hardness or a reduction in the notch ductility of the material. Detailed information on embrittlement mechanisms and the resulting fracture appearance can be found in the article "Visual Examination and Light Microscopy" in *Fractography,* Volume 12 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Temper embrittlement causes a significant increase in the brittle-to-ductile transition temperature of low-alloy steels containing 1 to 3% Cr that are exposed to above 370 to 540 °C (700 to 1000 °F) for some period of time. Brittle failure at weld defects can occur when process equipment made from these steels is fully pressurized during start-up or shutdown. Therefore, pressure should be limited to 25% of design when temperatures are below 150 °C (300 °F) (Ref 22). Ideally, equipment made from steels that have become temper embrittled should be preheated to above 120 °C (250 °F) before pressurization following a shutdown. Temper embrittlement is caused by the segregation of residual steel elements to the grain boundaries, and this greatly reduces the intercrystalline strength. Limiting the acceptance levels of such elements as manganese, silicon, phosphorus, tin, antimony, and arsenic can improve the temper embrittlement resistance of 2.25Cr-0.5Mo, 2.25Cr-1Mo, and 3Cr-1Mo steels. Frequent nondestructive testing of major weld seams is recommended to determine if equipment has become embrittled.

885-°F (475-°C) Embrittlement. Another embrittling phenomenon, referred to as 885 Embrittlement, occurs with ferritic stainless steels containing 12% or more chromium after long-term exposure to temperatures between 400 and 540 °C (750 and 1000 °F). Heat treatment at about 620 °C (1150 °F), followed by rapid cooling, will restore ductility to embrittled low-alloy and ferritic stainless steels.

Sigma-phase embrittlement can occur in austenitic stainless as well as in straight-chromium stainless steels. Of the austenitic stainless steels, the most susceptible compositions contain approximately 25% Cr and 20% Ni. The straight-chromium steels that are most susceptible to σ-phase formation contain 17% or more chromium. Sigma-phase formation increases room-temperature tensile strength and hardness while decreasing ductility to the point of extreme brittleness. As a result, cracks are very likely to develop during cooling from operating temperatures. Sigma phase most commonly forms in equipment operating in a temperature range of 650 to 750 °C (1200 to 1400 °F). Because σphase can be dissolved at temperatures above 980 °C (1800 °F), the original properties of stainless steels can be restored by a suitable heat treatment.

Creep embrittlement is the stress-dependent embrittlement of low-alloy steels operating in the creep range. The result is a reduction in the stress rupture ductility. Creep embrittlement is caused by the formation of precipitates within the grains and by elongated grain-boundary carbides. Detrimental effects can be eliminated by annealing the steel.

Fabricability

With very few exceptions, process equipment and piping are fabricated by welding wrought steels. The shells of pressure vessels are usually made from rolled plate, while nozzles are forgings. This requires that the steels have sufficient ductility for forming and are readily weldable. Weldability of steels is important not only for initial fabrication but also for future field repairs or modifications. Weld repairs and postweld heat treatments can affect the mechanical properties of components that have been normalized or quenched and tempered.

Welding may result in certain other problems. Hydrogen dissolved in liquid weld metal can cause cracking during solidification, as well as embrittlement of the weld. The risk is reduced by the use of low-hydrogen electrodes, careful drying of electrodes, and close control of pre- and postweld heat treatments. Stress relief or reheat cracking is intergranular cracking in the weld heat-affected zone (HAZ). The HAZ cracking occurs when weldments are heated during postweld heat treatment, or it occurs by subsequent exposure to elevated service temperatures. Low-alloy steels are especially susceptible to the above phenomena, but hydrogen cracking can occur with any of the ferritic steels if proper care is not taken.

Corrosion Resistance

The effects of the environment need to be considered when materials of construction are specified. General corrosion (uniform metal loss) is the easiest form of metal deterioration that can be considered in the design phase because additional metal can be provided in the form of a corrosion allowance. It is also the easiest form of corrosion that can be detected by nondestructive testing techniques. In the case of pitting corrosion, it is possible to provide a pitting allowance. Because metal loss due to general corrosion is often not significant under pitting conditions, this approach would represent a rather expensive method of protecting equipment. Instead, it would be more practical to avoid process conditions that produce pitting or to change to a material that will not pit. Stress-corrosion cracking is one of the most serious forms of metal deterioration because it can result in the complete fracture of equipment and considerable losses to an operating facility. Stress-corrosion cracks are very difficult to detect because they may occur during operation and because they are usually not uniformly distributed over the metal surfaces. Austenitic stainless steels are highly susceptible to SCC and consequently are usually avoided for the primary pressure boundary of components. However, they are used as protective, internal linings.

Corrosion

For practical purposes, corrosion in refineries and petrochemical plants can be classified into low-temperature corrosion and high-temperature corrosion (Ref 23, 24). Low-temperature corrosion is considered to occur below approximately 260 °C (500 °F) in the presence of water. Carbon steel can be used to handle most hydrocarbon streams in this temperature range, except where aqueous corrosion by inorganic contamination, such as hydrogen chloride or hydrogen sulfide, necessitates selective application of more resistant alloys. High-temperature corrosion is considered to take place above approximately 260 °C (500 °F). The presence of water is not necessary, because corrosion occurs by the direct reaction between metal and environment.

Low-Temperature Corrosion

Most corrosion problems in refineries are not caused by hydrocarbons that are processed but by various inorganic compounds, such as water, hydrogen sulfide, hydrochloric acid, hydrofluoric acid, sulfuric acid, and caustic (Ref 25). There are two principal sources of these compounds: feed-stock contaminants and process chemicals, including solvents, neutralizers, and catalysts. Generally, the same applies to corrosion problems in petrochemical plants except that corrosion is also caused by organic acids, such as acetic acid, that may be used as solvents. In addition, corrosion problems are caused by the atmosphere, cooling water, boiler feedwater, steam condensate, and soil.

Low-Temperature Corrosion by Feed-Stock Contaminants

The major cause of low-temperature (and, for that matter, high-temperature) refinery corrosion is the presence of contaminants in crude oil as it is produced. Although some contaminants are removed during preliminary treating in the fields, most end up in refinery tankage, along with contaminants picked up in pipelines or marine tankers. In most cases, the actual corrosives are formed during initial refinery operations. For example, potentially corrosive hydrogen chloride evolves in crude preheat furnaces from relatively harmless calcium and magnesium chlorides entrained in crude oil (Ref 26). In petrochemical plants, certain corrosives may have been introduced from upstream refinery and other process operations. Other corrosives can form from corrosion products after exposure to air during shutdowns; polythionic acids fall into this category. The following discussion will focus on the most important crude oil contaminants that have caused corrosion problems.

Air. During shutdowns or turnarounds, most plant equipment is exposed to air. Air also can enter the suction side of pumps if seals or connections are not tight. In general, the air contamination of hydrocarbon streams has been more detrimental with regard to fouling than corrosion. However, air contamination has been cited as a cause of accelerated corrosion in vacuum transfer lines and vacuum towers of crude distillation units. Air contamination has supposedly

increased the overhead corrosion of crude distillation towers, but this has been difficult to reconcile with the fact that oxygen in air reacts with hydrogen sulfide to form polysulfides, which tend to inhibit corrosion.

Water. Water is found in all crude oils and is difficult to remove completely. In addition, water originates with stripping steam for fractionation towers and is produced in hydrotreating operations. Water not only functions as an electrolyte but also hydrolyzes certain inorganic chlorides to hydrogen chloride, as noted above. Water is primarily responsible for various forms of corrosion in fractionation tower overhead systems. In general, whenever equipment can be kept dry through suitable process or equipment changes, corrosion problems will be minimized.

The combination of water and air can be especially detrimental. Moisture and air are drawn into storage tanks during normal breathing as a result of pumping and changes in temperature. Tank activity and corrosion are closely interrelated. Because crude and heavy oils form a protective oil film on the working areas of a tank shell, corrosion is generally limited to the top shell ring and the underside of the roof. Tank bottom corrosion occurs mostly with crude oil tanks and is caused by water and salt entrained in the crude oil. A layer of water usually settles out and can become highly corrosive. Alternate exposure to sour crude oils and salt water causes especially severe corrosion (Ref 27). Mill scale tends to accelerate tank bottom corrosion because cracks in the mill scale form anodic areas that pit, while the remaining mill scale acts as the cathode.

Light stocks do not form protective oil films, and corrosion occurs primarily at the middle shell rings because these are exposed to more wetting and drying cycles than other tank areas (Ref 28). Corrosion is in the form of pitting under globules of water that attach themselves to the tank wall. Pitting becomes so extensive that metal loss appears as more or less uniform corrosion. The rate of corrosion is proportional to the water and air content of light stocks. Contamination from chloride and hydrogen sulfide accelerates attack.

Hydrogen Sulfide. Sour crude oils and gases that contain hydrogen sulfide are handled by most refineries (Ref 29). Hydrogen sulfide is also present in some feed stocks handled by petrochemical plants. During processing at elevated temperatures, hydrogen sulfide is also formed by the decomposition of organic sulfur compounds that are present. Corrosion of steel by hydrogen sulfide forms the familiar black sulfide film seen in almost all refinery equipment (Ref 30). Hydrogen sulfide is the main constituent of refinery sour waters and can cause severe corrosion problems in overhead systems of certain fractionation towers, in hydrocracker and hydrotreater effluent streams, in the vapor recovery (light ends) section of fluid catalytic cracking units, in sour water stripping units, and in sulfur recovery units (Ref 31, 32). These will be discussed in greater detail in the section "Sour Water" in this article.

In general, carbon steel has fairly good resistance to aqueous sulfide corrosion because a protective iron sulfide film is formed (Ref 33). To avoid hydrogen stress cracking (sulfide cracking), hard welds (above 200 HB) must be avoided, if necessary, through suitable postweld heat treatment (Ref 34). Excessive localized corrosion in vessels has been resolved by selective lining with alloy 400 (N04400), but this alloy can be less resistant than carbon steel to aqueous sulfide corrosion at temperatures above 150 °C (300 °F). If significant amounts of chlorides are not present, lining vessels with type 405 (S40500) or type 304 (S30400) stainless steel can be considered. More recently, titanium grade 2 (R50400) tubes have been used as replacements for carbon steel tubes to control aqueous sulfide corrosion in heat exchangers at a number of units (Ref 35, 36).

Hydrogen Chloride. In refineries, corrosion by hydrogen chloride is primarily a problem in crude distillation units and, to a lesser degree, in reforming and hydrotreating units. In petrochemical plants, hydrogen chloride contamination can be present in certain feed stocks or can be formed by the hydrolysis of aluminum chloride catalyst.

In most production wells, chloride salts are found either dissolved in water that is emulsified in crude oil or as suspended solids. Salts also originate from brines injected for secondary recovery or from seawater ballast in marine tankers. Typically, the salts in crude oils consist of 75% sodium chloride, 15% magnesium chloride, and 10% calcium chloride (Ref 37). When crude oils are charged to crude distillation units and heated to temperatures above approximately 120 °C (250 °F), hydrogen chloride is evolved from magnesium and calcium chloride, while sodium chloride is essentially stable up to roughly 760 °C (1400 °F). Hydrogen chloride evolution takes place primarily in crude preheat furnaces. Dry hydrogen chloride, especially in the presence of large amounts of hydrocarbon vapor or liquid, is not corrosive to carbon steel (Ref 38).

When steam is added, however, to the bottom of the crude tower to facilitate fractionation, dilute hydrochloric acid forms in the top of the tower and in the overhead condensing system. Severe aqueous chloride corrosion of carbon steel components can occur at temperatures below the initial water dew point (Ref 39). Corrosion rate increases with a decrease

in pH value of overhead condensate water. Corrosion is mostly in the form of droplet-impingement attack at elbows of the overhead vapor line and at inlets of overhead condensers. Corrosion also occurs on condenser tubes that are at the temperatures where most of the water condenses out. Often, droplets of dilute hydrochloric acid become entrapped under deposits that are present on tower trays, in condenser shells, and at baffles. The resultant underdeposit corrosion is highly localized and usually quite severe.

Overhead condensing systems of both the crude and vacuum towers of crude distillation units are generally made from carbon steel. Coolers and condensers in cooling-water service usually use admiralty metal (C44300) tubes to reduce corrosion and fouling on the water side. Where aqueous chloride corrosion is a problem on the process side, titanium grade 2 (R50400) tubes should be considered. The top of the crude tower can be lined with alloy 400 (A04400), and tray components made from alloy 400 (N04400) can be used for the upper five or so trays to combat aqueous chloride corrosion. Alloy 400 (N04400) tubes usually have not been cost effective in overhead coolers and condensers, but alloy 400 (N04400) has been successfully used for selective strip lining of those areas of the overhead system were excessive corrosion occurs despite the implementation of other corrosion control measures.

To minimize aqueous chloride corrosion in the overhead system of crude towers, it is best to keep the salt content of the crude oil charge as low as possible, preferably below 1 pound per thousand barrels (PTB), corresponding to roughly 4 ppm. This is done by proper tank-settling, desalting, or, if necessary, double desalting (Ref 40, 41, 42). Another way to reduce overhead corrosion would be to inject caustic (sodium hydroxide) into the crude oil downstream of the desalter. Up to 3 PTB (10 ppm) caustic can usually be tolerated from a process point of view, while higher concentrations increase fouling of crude preheat exchangers, boiler corrosion by sodium vanadate (when reduced crude is burned as boiler fuel), or coking in lines and heaters of coking units (Ref 43). Caustic should not be used when reduced crude is charged directly to catalytic cracking or hydrotreating units, because of possible catalyst deactivation.

Neutralizers are injected into the overhead vapor line of the crude tower to maintain the pH value of stripping steam condensate between 5 and 6 (Ref 44, 45, 46, 47). A pH value above 7 can increase corrosion with sour crudes, as well as fouling and underdeposit corrosion by neutralizer chloride salts. Where fouling becomes a problem, water should be injected, either intermittently or continuously, to dissolve salt deposits in those areas of the overhead system that are not exposed to stripping-steam condensate (Ref 48). Filming-amine corrosion inhibitors can be injected into the overhead vapor line to provide additional insurance against excessive corrosion (Ref 49, 50, 51).

In downstream refining equipment, chlorides accelerate corrosion by penetrating protective surface films, increasing electrolyte conductivity, or complexing with steel surfaces (Ref 52). In reforming units, organic chlorides are often used to regenerate reformer catalyst. Hydrogen chloride is stripped off the catalyst if excessive moisture is present in the reformer feed; this causes increased corrosion, not only in reforming units but also in hydrotreating units that use excess hydrogen (make-gas) from the reformer. As in the case of crude distillation units, water washing and injection of neutralizers and/or filming-amine corrosion inhibitors can be used to control fouling and corrosion by chloride salts. Hydrogen make-gas can be passed through a water scrubber to remove hydrogen chloride. Selective alloying with alloy 825 (N08825), alloy 400 (N04400), or titanium grade 2 (R50400) can be required to control chloride attack in heat exchangers and separator drums.

Nitrogen Compounds. Organic nitrogen compounds, such as indole, carbuzole, pyridine, or quinoline, are present in many crude oils, but do not contribute to corrosion problems unless converted to ammonia or hydrogen cyanide (Ref 53). This occurs primarily in catalytic cracking, hydrotreating, and hydrocracking operations where ammonia and hydrogen cyanide, in combination with hydrogen sulfide and other constituents, become the major constituents of sour water than can be highly corrosive to carbon steel (Ref 54).

Ammonia is also produced in ammonia plants to become a raw material for the manufacture of urea and other nitrogen-base fertilizers. Ammonia in synthesis gas at temperatures between 450 and 500 °C (840 and 930 °F) causes nitriding of steel components. When synthesis gas is compressed to up to 34.5 MPa (5000 psig) prior to conversion, corrosive ammonium carbonate is formed, requiring various stainless steels for critical components. Condensed ammonia is also corrosive and can cause SCC of stressed carbon steel and low-alloy steel components (Ref 55).

Sour Water. The term sour water denotes various types of process water containing primarily hydrogen sulfide, ammonia, and hydrogen cyanide, often in combination with certain other organic and inorganic compounds, including phenols, mercaptans, chlorides, and fluorides. Sour waters are removed from refining units by settling in overhead reflux drums, separator drums, water coalescer drums, and other specialized equipment. Depending on their exact composition, sour waters can become highly corrosive. Sour water corrosion is of particular concern in the vapor recovery (light ends) section of catalytic cracking units and in reactor effluent and light ends sections of hydrotreating and hydrocracking units,

in which high concentrations of ammonia can saturate process water with ammonium bisulfide and cause serious corrosion of carbon steel components. Ammonium bisulfide will also rapidly attack admiralty metal (C44300) tubes. Sour water corrosion is a major problem at some sour water stripping units, in which exceptionally high concentrations of ammonium bisulfide build up in the thin film of condensed water on overhead condenser tubes. The resultant corrosion can be so severe that even tubes made from austenitic stainless steels are attacked, and only titanium grade 2 (R50400) tubes have sufficient resistance to be used in this service.

Normally, all components in the vapor recovery (light ends) sections of catalytic cracking units are made of carbon steel. Exceptions to this rule include tower internals made of type 405 (S40500) or 410 (S41000) stainless steel and tubes in overhead condensers and compressor aftercoolers made from admiralty metal (C44300), alloy 400 (N04400), or titanium grade 2 (R50400). Corrosion problems of carbon steel components are often closely associated with hydrogen blistering. Admiralty metal (C44300) tubes in overhead condensers may typically last only 5 years, with leaks finally occurring as a result of ammonia SCC. Depending on the particular process conditions, admiralty metal (C44300) tubes can also corrode by severe localized attack. Admiralty metal (C44300) tubes in compressor aftercoolers often need to be replaced with titanium grade 2 (R50400) tubes. The biggest recurring problem has been corrosion and hydrogen blistering of carbon steel in coolers, separator drums, absorber/stripper towers, and, occasionally, overhead condensers at a number of locations. These will be discussed in greater detail in the section "Hydrogen Blistering" in this article.

Components in hydrotreating and hydrocracking units that operate at temperatures below about 260 °C (500 °F) are typically made from carbon steel. Where aqueous ammonium bisulfide corrosion becomes a problem, generous corrosion allowances may have to be provided for carbon steel (Ref 56, 57). Selective alloying with alloy 825 (N08825), alloy 400 (N04400) or titanium grade 2 (R50400) may be required for heat exchangers and separator drums to control excessive corrosion. On some units, corrosion is accompanied by hydrogen blistering. Hydrotreating and hydrocracking units that experience fouling problems due to ammonium sulfide or ammonium chloride deposition may require intermittent or continuous water injection to dissolve these salt deposits. It is of prime importance, however, that sufficient coalescer capacity be available or provided in order to ensure that the injected water is removed. Otherwise, serious corrosion can occur when the water ends up in downstream equipment.

All equipment and piping of reforming units that operate at below approximately 260 °C (500 °F) are usually made from carbon steel. Although admiralty metal (C44300) tubes are often used in water-cooled effluent cooler and condensers, chloride attack may necessitate selective alloying with alloy 400 (N04400) or titanium grade 2 (R50400). In some cases, carbon steel tubes are superior to admiralty metal (C44300) tubes, provided the cooling water is properly treated. Similar considerations apply to water-cooled coolers and condensers in the overhead systems of prefractionator, splitter, debutanizer, and other fractionation towers. Filming-amine corrosion inhibitors can be used to help control overhead corrosion.

The principal material of construction for sour water stripping units is carbon steel. There are several varieties of sour water strippers, but nonacidified condensing and noncondensing strippers are most commonly used (Ref 58, 59). The stripping medium is primarily steam. Stripper towers are generally made from carbon steel with type 316 (S31600) stainless steel, aluminum, or carbon steel internals, depending on corrosion experience. To control tower corrosion, a minimum top temperature of 80 °C (180 °F) is required. Below this temperature, hydrogen sulfide will concentrate in the upper part of the tower but will not be carried overhead. Feed charge pumps are usually made from cast iron or cast steel, including the impellers. Feed piping, bottoms piping, and the feed/bottoms heat exchanger can be made from carbon steel. Carbon steel has also been satisfactory for stripper reboilers that may be used instead of live stripping steam. Thermosyphon reboilers (with sour water in the tubes) are recommended over kettle reboilers because the latter are often prone to fouling and resultant underdeposit corrosion.

Most corrosion problems have been in overhead condensers of condensing sour water strippers (Ref 60). Although a variety of alloys have been used for overhead condenser tubes, only aluminum and titanium grade 2 (R50400) can be relied on to provide adequate resistance to the highly corrosive conditions encountered in many overhead systems. Carbon steel is usually satisfactory for the overhead vapor line, condenser shell, run down lines, accumulator drum, and reflux lines. All welds in these components should be postweld heat treated to avoid hydrogen stress cracking. Reflux pumps can be made of carbon steel or type 304 (S30400) stainless steel, but for optimum performance, alloy 20 (N08020) is recommended. Hydrogen blistering often accompanies corrosion in overhead condenser shells and reflux drums. Water-soluble filming-amine corrosion inhibitors can be injected into the overhead vapor line to help control both corrosion and hydrogen blistering. Few, if any, corrosion problems have been experienced with noncondensing sour water strippers.

Serious sour water corrosion of carbon steel components can occur in the overhead system of amine regenerators (strippers) of gas-treating or sulfur recovery units, especially if all of the water condensate is returned to the tower as

reflux. Corrosion is usually accompanied by hydrogen blistering. Continuous or periodic blowdown of sour water to the sour water stripping unit should be employed to lower the concentrations of hydrogen sulfide, ammonia, and cyanide in the overhead water condensate. If this fails to control corrosion, carbon steel condenser tubes may have to be replaced with titanium grade 2 (R50400) tubes. In addition, corrosion can be minimized by operating the regenerator so that roughly 0.5% amine is taken overhead to act as a corrosion inhibitor.

Polythionic Acids. Combustion of H_2S in refinery flares can produce polythionic acids of the type $H_2S_xO_y$ (including sulfurous acid) and cause severe intergranular corrosion of flare tips made of stainless steels and high-nickel alloys (Ref 61). Corrosion can be minimized by using nickel alloys, such as alloy 825 (N08825) or alloy 625 (N06625). Polythionic acids also cause SCC during shutdown, as discussed in the section "SCC and Embrittlement" in this article.

Low-Temperature Corrosion by Process Chemicals

Severe corrosion problems can be caused by process chemicals, such as various alkylation catalysts, certain alkylation by-products, organic acid solvents used in certain petrochemical processes, hydrogen chloride stripped off reformer catalyst, and caustic and other neutralizers that, ironically, are added to control acid corrosion. Filming-amine corrosion inhibitors can be quite corrosive if injected undiluted (neat) into a hot vapor stream. Another group of process chemicals that are corrosive, or become corrosive, is solvents used in treating and gas-scrubbing operations.

Acetic Acid. Corrosion by acetic acid can be a problem in petrochemical process units for the manufacture of certain organic intermediates, such as terephthalic acid. Various types of austenitic stainless steels are used, as well as alloy C-4 (N06455), alloy C-276 (N10276), and titanium, to control corrosion by acetic acid in the presence of small amounts of hydrogen bromide or hydrogen chloride.

As a rule, even tenths of a percent of water in acetic acid can have a significant influence on corrosion. Type 304 (S30400) stainless steel usually has sufficient resistance to the lower concentrations of acetic acid up to the boiling point. Higher concentrations can also be handled by type 304 (S30400) stainless steel if the temperature is below about 90 °C (190 °F). Increasing the chromium and/or nickel content has little effect on resistance to acetic acid. Addition of molybdenum, however, markedly increases the resistance of austenitic stainless steels, and type 316 (S31600) and type 317 (S31700) stainless steels are used for the overwhelming majority of hot acetic acid applications. Corrosion by acetic acid increases with temperature. Bromide and chloride contamination causes pitting and SCC, while addition of oxidizing agents, including air, can reduce corrosion rates by several orders of magnitude.

Aluminum Chloride. Certain refining and petrochemical processes, such as butane isomerization, ethylbenzene production, and polybutene production, use aluminum chloride as a catalyst (Ref 62). Aluminum chloride is not corrosive if it is kept absolutely dry. If traces of water or water vapor are present in hydrocarbon streams, aluminum chloride hydrolyzes to hydrochloric acid, which can of course be highly corrosive. To control corrosion in the presence of aluminum chloride, feed is dried in calcium chloride dryers. During shutdowns, equipment should be opened for the shortest possible time. Upon closing, it should be dried with hot air, followed by inert gas blanketing. Equipment that is exposed to hydrochloric acid may require extensive lining with nickel alloys, such as alloy 400 (N04400), B-2 (N10665), C-4 (N06455), or C-276 (N10276) (Ref 63).

Organic Chlorides. Organic chlorides in crude oils will form various amounts of hydrogen chloride at the elevated temperatures of crude preheat furnaces, depending on the chlorides involved. Many crude oils contain small amounts of organic chlorides (5 to 50 ppm), but the major problem is contamination with organic chloride solvents during production. Although major producers are aware of the problem, some small operators may still use organic chloride solvents to remove wax deposits in oil field tankage and associated equipment and piping. Spent solvent is then simply added to the crude oil. Organic chloride solvents are also extensively used for metal-degreasing operations in and out of the refinery. Spent solvent is often discarded with slop oil, which is added to the crude oil and charged to the crude distillation unit.

Contaminated crude oils have been found to contain as much as 7000 ppm chlorinated hydrocarbons. Such crude oils not only cause severe corrosion in the overhead system of crude distillation towers but also affect reformer operations (Ref 64). Typical problems in the latter category include runaway cracking, rapid coke accumulation on the catalyst, and increased corrosion in fractionator overhead systems (Ref 65, 66). Obviously, every effort must be made to avoid charging contaminated crude oil. Organic chlorides cannot be removed by desalting. If contaminated crude oil must be run off, the usual approach is to blend it slowly into uncontaminated crude oil.

Hydrogen Fluoride. Some alkylation processes use concentrated hydrofluoric acid instead of sulfuric acid as the catalyst. In general, hydrofluoric acid is less corrosive than hydrochloric acid because it passivates most metals by the formation of protective fluoride films. If these films are destroyed by diluted acid, severe corrosion occurs. Therefore, as long as feed stocks are kept dry, carbon steel--with various corrosion allowances--can be used for vessels, piping, and valve bodies of hydrofluoric acid alkylation units. Alloy 400 (N04400) is used selectively at locations where excessive corrosion has been experience. Hydrofluoric acid can cause hydrogen blistering of carbon steel equipment and hydrogen stress cracking of hardened bolts (Ref 67).

By following proper design practices and prescribed maintenance procedures and by diligently keeping feeds stocks and equipment dry, there will be few corrosion problems. All carbon steel welds that contact hydrofluoric acid should be postweld heat treated (Ref 68). This applies especially to welds in various vessels. Vessels should be radiographed to check for slag inclusions in plates and welds; slag inclusions are attacked by hydrofluoric acid. Hydrofluoric acid has the capability of finding the smallest holes in welds or threads. During welding, each preceding pass must be properly cleaned. All threaded connections should be seal welded. Where leaks do show up after start-up, small holes can often be peened shut, or small bits of copper or lead can be peened into larger holes to seal a leak. Any subsequent repair welds should also be postweld heat treated.

Fractionation towers should have type 410 (S41000) stainless steel tray valves and bolting; alloy 400 (N04400) tray valves and bolting are preferred for the deisobutanizer tower. The acid rerun tower usually requires cladding with alloy 400 (N04400) and alloy 400 (N04400) tray components. To avoid SCC, alloy 400 (N04400) welds that contact hydrofluoric acid should be postweld heat treated. No asbestos gasketing should be used on trays. Soft iron gaskets are used on channel head-to-shell joints of heat exchangers. Spiral-wound alloy 400/Teflon gaskets are also used but are more expensive. Carbon steel U-tube bundles are preferred for all exchangers that contact hydrofluoric acid; alloy 400 (N04400) tubes have been found to offer few advantages (Ref 69). Tube ends and tubesheet holes should be carefully cleaned to ensure tube rolls that are tight against hydrofluoric acid. Seal welding of tubes may be required. Internal bolting should not be used in exchangers.

The piping is generally carbon steel with welded connections that have received postweld heat treatment. All taps should be self-draining and should have double block valves. Instrument connections should be made from the top. Valve bodies on gate and plug valves are usually carbon steel, with Teflon packing and Teflon seats. Relief valves should have alloy 400 (N04400) trim. Teflon tape sealing should be used on any threaded connections. Pumps in hydrofluoric acid service normally have carbon steel casings that are weld overlayed with alloy 400 (N04400). Impellers and sleeves should be alloy 400 (N04400); shafts should be alloy K 500 (N05500).

Specific areas where corrosion is likely to occur include the bottom of the acid rerun tower, the feed inlet areas of the deisobutanizer and depropanizer towers, the overhead condensers of these towers, the reboiler of the propane stripper, and piping around the acid rerun tower (Ref 70). Trouble areas in vessels are often selectively strip lined with alloy 400 (N04400). Dimpling of tray valve caps during manufacture reduces their tendency to stick to trays because of corrosion products. Alloy 400 (N04400) piping is used to replace carbon steel piping, which corrodes at excessive rates; welds should be postweld heat treated.

Experience has shown that most corrosion problems in hydrofluoric acid alkylation units occur after shutdowns because pockets of water have been left in the equipment. This water is from the neutralization and washing operation required for personnel safety before the equipment can be opened for inspection. It is very important that equipment be thoroughly dried by draining all low spots and by circulating hydrocarbon before the introduction of hydrofluoric acid catalyst at start-up. Corrosion by hydrofluoric acid is occasionally accompanied by hydrogen blistering. Filming-amine corrosion inhibitors have been injected into the overhead systems of various towers, sometimes in conjunction with injection of dilute soda ash solutions. Because the primary goal of proper operations is to keep the unit as dry as possible, intentional addition of water in any form should be considered only as a last resort.

Sulfuric Acid. Certain alkylation units use essentially concentrated sulfuric acid as the catalyst; some of this sulfuric acid is entrained in reactor effluent and must be removed by neutralization with caustic and scrubbing with water. Acid removal may not be complete, however, and traces of acid--at various concentrations (in terms of water)--remain in the stream. Sulfuric acid can be highly corrosive to carbon steel, which is the principal material of construction for sulfuric acid alkylation units. Because the boiling point of sulfuric acid ranges from 165 to 315 °C (330 to 600 °F), depending on concentration, entrained acid usually ends up in the bottom of the first fractionation tower and reboiler following the reactor; this is where the entrained acid becomes concentrated.

Acid concentrations above 85% by weight are usually not corrosive to carbon steel if temperatures are below 40 °C (100 °F). Cold-worked metal (usually bends) should be stress relieved. Under ideal operating conditions, few, if any, corrosion and fouling problems occur (Ref 71, 72).

Carbon steel depends on a film of iron sulfate for corrosion resistance, and if its film is destroyed by high velocities and flow turbulence, corrosion can be quite severe. For this reason, flow velocities should be below 1.2 m/s (4 ft/s). Attack in the form of erosion-corrosion can occur at piping welds that have not received postweld heat treatment. This highly localized attack immediately downstream of piping welds has been attributed to a spheroidized structure; a normalizing postweld heat treatment at 870 °C (1600 °) is required to minimize corrosion (Ref 73). Erosion-corrosion is also a problem at other locations of high turbulence or velocity (Ref 74). Alloy 20 (N08020) is more resistant than carbon steel to this type of corrosion. In extreme cases, however, even alloy 20 (N08020) will be damaged by erosion-corrosion, and the selective use of alloy B-2 (N10665) may be required.

Carbon steel valves usually require alloy 20 (N08020) internals or trim because even slight attack of carbon steel seating surfaces is sufficient to cause leakage (Ref 75). Pump internals and injection and mixing nozzles in concentrated or spent sulfuric acid service are often made of alloy 20 (N08020), alloy B-2 (N10665), and alloy C-4 (N10002) or C-276 (N10276). For hydrocarbon streams containing only traces of concentrated or dilute sulfuric acid, steel-body valves with type 316 (S31600) stainless steel trim can be used. In this service, steel pump casings that are weld overlayed with aluminum bronze have been successfully used. Pump impellers made from high-silicon cast iron are often used.

Piping for hydrocarbon/acid mixing lines ahead of the reactors may require alloy 20 (N08020), because water contamination of feed stocks can cause severe corrosion of carbon steel. Alloy 400 (N04400) has been found to be useful for reactor effluent lines around the caustic and wash-water injection points. Valve trays in fractionation towers require type 405 (S40500) or (S41000) stainless steel tray valves and bolting. In general, organic coatings are not resistant to concentrated sulfuric acid. Teflon has excellent resistance to sulfuric acid and is extensively used for gaskets, pump valve packing, and mixing nozzles.

In addition to sulfuric acid, reactor effluent contains traces of alkyl and dialkyl sulfates from secondary alkylation reactions (Ref 76). These esters decompose in reboilers to form sulfur dioxide and polymeric compounds (the latter are notorious foulants). Sulfur dioxide combines readily with water in the upper part and overhead system of fractionation towers; the resultant sulfurous acid can cause severe corrosion in overhead condensers. In some units, carbon steel or admiralty metal (C44300) tubes in overhead condensers, particularly those of the deisobutanizer tower, may have to be replaced with alloy 400 (N04400) or titanium grade 2 (R50400) tubes. As a rule, however, titanium is not resistant to sulfuric acid corrosion. Neutralizers can be injected into the overhead vapor lines of various towers to maintain the pH value of aqueous condensate near 7. Filming-amine corrosion inhibitors can also be injected.

Caustic. Sodium hydroxide is widely used in refinery and petrochemical plant operations to neutralize acidic constituents. At ambient temperature and under dry conditions, caustic can be handled in carbon steel equipment. Carbon steel is also satisfactory for aqueous caustic solutions between 50 and 80 °C (120 and 180 °F), depending on concentration. For caustic service above these temperatures but below approximately 95 °C (200 °F), carbon steel can also be used if it has been postweld heat treated to avoid SCC at welds. Austenitic stainless steels, such as type 304 (S30400), can be used up to approximately 120 °C (250 °F), while nickel alloys are required at higher temperatures.

Severe caustic corrosion of the crude transfer line, which is immediately downstream of the caustic injection point, can occur in crude distillation units when 40% (by weight) caustic solution is injected into hot, desalted crude oil to neutralize any remaining hydrogen chloride. Predilution of the caustic with water to form a 3% (by weight) solution minimizes this problem. Better dispersion of the more diluted solution in the hot crude oil prevents puddles of molten caustic from collecting along the bottom of the transfer line. If caustic is injected too close to an elbow of the transfer line, impingement by droplets of caustic can cause severe attack and hole-through at the elbow.

There are some unusual situations in which caustic corrosion is encountered. For example, traces of caustic can become concentrated in boiler feedwater and cause corrosion (gouging) and SCC (caustic embrittlement). This occurs in boiler tubes that alternate between wet and dry conditions (steam blanketing) because of overfiring. In some petrochemical processes, caustic gouging is found under deposits in heat exchangers that remove heat by generation of steam. For example, vertical heat exchangers for cracked gas in ethylene units are especially vulnerable if deposits are allowed to accumulate on the bottom tubesheet. Boiler feedwater permeates these deposits and evaporates, and this causes the caustic to concentrate in any liquid that is left behind. The caustic content of such trapped liquid can reach several percent, which is more than enough to destroy the normally protective iron oxide (magnetite) film on boiler steel and thus cause severe corrosion.

Amines. Corrosion of carbon steel by amines in gas-treating and sulfur recovery units can usually be traced to faulty plant design, poor operating practices, and solution contamination (Ref 77). In general, corrosion is most severe in systems removing only carbon dioxide and is least severe in systems removing only hydrogen sulfide. Systems handling mixtures of the two fall between these two extremes if the gases contain at least 1 vol% hydrogen sulfide. Corrosion in amine plants using monoethanolamine is more severe than in those using diethanolamine, because the former is more prone to degradation.

Corrosion is not caused by the amine itself, but is caused by dissolved hydrogen sulfide or carbon dioxide and by amine degradation products (Ref 78). Corrosion is most severe at locations where acid gases are desorbed or removed from rich amine solution. Here, temperatures and flow turbulence are highest. This includes the regenerator (stripper) reboiler and lower portions of the regenerator itself (Ref 79). Corrosion can also be a significant problem on the rich-amine side of the lean/rich-amine exchanger, in amine solution pumps, and in reclaimers. Hydrogen blistering has been a problem in the bottom of the contactor (absorber) tower and in regenerator overhead condensers and reflux drums (Ref 80).

The common material of construction for amine units is carbon steel. To prevent alkaline SCC, welds of components in both lean and rich-amine service should be postweld heat treated regardless of service temperature (Ref 81). Postweld heat treatment also protects against hydrogen stress cracking. On the whole, there have been relatively few corrosion problems in most amine units.

Operating guidelines usually set limits on amine concentration (20%), acid-gas loading (0.35 mol per mole of amine), and reboiler steam temperature (150 °C, or 300 °F) (Ref 82, 83). These guidelines should be followed to minimize corrosion. Sidestream filtration is also extremely beneficial. Filming-amine corrosion inhibitors are often ineffective. Several proprietary oxidizing corrosion inhibitors based on sodium metavanadate are available. These have been successfully used in certain cases, but licensing costs tend to be high for any but the smaller units.

Regenerator towers usually should be lined with type 405 (S40500) stainless steel, and tower internals are often made of type 304 (S30400) stainless steel. Where applicable, type 304 (S30400) stainless steel is required for the rich-amine pressure of the let-down valve, as well as for piping downstream of the let-down valve, to control corrosion accelerated by high flow turbulence.

Corrosion in the regenerator reboiler is usually in the form of pitting and groove-type corrosion of tubes and is caused by localized overheating inside baffle holes (Ref 84). If thermosyphon reboilers are undersized, part of the tube bundle will become vapor blanketed, and the tubes will overheat. Subsequent exposure of the hot tubes to amine solution will cause severe turbulence and velocity-accelerated corrosion. Vapor blanketing also occurs if tubes are allowed to fill partially with steam condensate; this reduces the amount of tube surface available for heat transfer and increases the heat flux through the remainder of the tubes. Unless faulty reboiler operation can be corrected, carbon steel tubes may have to be replaced with type 304 (S30400) or 316 (S31600) stainless steel tubes. Alloy 400 (N04400) reboiler tubes have been successfully used in amine units that handle only carbon dioxide.

As a rule, carbon steel tubes are satisfactory for regenerator overhead condensers. As discussed in the section "Sour Water" in this article, high corrosion rates can occur at this location, and carbon steel tubes may have to be replaced with titanium grade 2 (R50400) tubes. Carbon steel tubes are used in reclaimers with proper neutralization of acidic constituents (Ref 85). Because the reclaimer can be taken out of service at any time, periodic retubing with carbon steel presents no problems. Cast iron pumps normally are used in low-pressure amine service. If corrosion problems occur, high-silicon cast iron impellers can be used. In high-pressure amine service type 316 (S31600) stainless steel pumps may be needed.

Phenol. Phenol (carbolic acid) is used in refineries to convert heavy, waxy distillates obtained by crude oil distillation into lubricating oils. As a rule, all components in the treating and raffinate recovery sections, except tubes in water-cooled heat exchangers, are made from carbon steel. If water is not present, few significant corrosion problems can be expected to occur in these sections. In the extract recovery section, however, severe corrosion can occur, especially where high flow turbulence is encountered. As a result, certain components require selective alloying with type 316 (S31600) stainless steel. Typically, stainless steel liners are required for the top of the dryer tower, the entire phenol flash tower, and various condenser shells and separator drums that handle phenolic water. Tubes and headers in the extract furnace should also be made of type 316 (S31600) stainless steel, with U-bends sleeved with alloy C-4 (N06455) on the outlet side to minimize velocity-accelerated corrosion.

High-Temperature Corrosion

High-temperature corrosion problems in refineries are of considerable importance (Ref 86). Equipment failures can have serious consequences because processes at high temperatures usually involve high pressures as well. With hydrocarbon streams, there is always the danger of fire when ruptures occur. On a more positive note, high-temperature refinery corrosion is primarily caused by various sulfur compounds originating with crude oil. Over the years, extensive research has been done to establish the mechanism of various forms of high-temperature sulfidic corrosion. Corrosion rate correlations are available; therefore, equipment life can be predicted with some degree of reliability.

Sulfidic Corrosion. Corrosion by various sulfur compounds at temperatures between 260 and 540 °C(500 and 1000 °F) is a common problem in many petroleum-refining processes and, occasionally, in petrochemical processes. Sulfur compounds originate with crude oils and include polysulfides, hydrogen sulfide, mercaptans, aliphatic sulfides, disulfides, and thiophenes (Ref 87). With the exception of thiophenes, sulfur compounds react with metal surfaces at elevated temperatures, forming metal sulfides, certain organic molecules, and hydrogen sulfide (Ref 88, 89). The relative corrosivity of sulfur compounds generally increases with temperature. Depending on the process particulars, corrosion is in the form of uniform thinning, localized attack, or erosion-corrosion. Corrosion control depends almost entirely on the formation of protective metal sulfide scales that exhibit parabolic growth behavior (Ref 90). In general, nickel and nickel-rich alloys are rapidly attacked by sulfur compounds at elevated temperatures, while chromium-containing steels provide excellent corrosion resistance (as does aluminum). The combination of hydrogen sulfide and hydrogen can be particularly corrosive, and as a rule, austenitic stainless steels are required for effective corrosion control.

Sulfidic Corrosion Without Hydrogen Present. This type of corrosion occurs primarily in various components of crude distillation units, catalytic cracking units, and hydrotreating and hydrocracking units upstream of the hydrogen injection line. Crude distillation units that process mostly sweet crude oils (less than 0.6% total sulfur, with essentially no hydrogen sulfide) experience relatively few corrosion problems. Preheat-exchanger tubes, furnace tubes, and transfer lines are generally made from carbon steel, as is corresponding equipment in the vacuum distillation section. The lower shell of distillation towers, where temperatures are above 230 °C (450 °F), is usually lined with stainless steel containing 12% Cr, such as type 405 (S40500). This prevents impingement attack under the highly turbulent flow conditions encountered, for example, near downcomers. For the same reason, trays are made of stainless steel containing 12% Cr. Even with low corrosion rates of carbon steel, certain tray components, such as tray valves, may fail in a short time because attack occurs from both sides of a relatively thin piece of metal.

Crude distillation units that process mostly sour crude oils require additional alloy protection against high-temperature sulfidic corrosion. The extent of alloying needed also depends on the design and the operating practices of a given unit. Typically, such units require low-alloy steels containing a minimum of 5% Cr for furnace tubes, headers and U-bends, and elbows and tees in transfer lines. In vacuum furnaces, tubes made from chromium steels containing 9% Cr are often used. Distillation towers are similar to those of units that process mostly sweet crude oils. Where corrosion problems persist, upgrading with steels containing a greater amount of chromium is indicated.

The high processing temperatures encountered in the reaction and catalyst regeneration section of catalytic cracking units require extensive use of refractory linings to protect all carbon steel components from oxidation and sulfidic corrosion. Refractory linings also provide protection against erosion by catalyst particles, particularly in cyclones, risers, standpipes, and slide valves. Stellite hardfacing is used on some components to protect against erosion. When there are no erosion problems and when protective linings are impractical, austenitic stainless steels, such as type 304 (S30400), can be used. Cyclone diplegs, air rings, and other internals in the catalyst regenerator are usually made from type 304 (S30400) stainless steel, as is piping for regenerator flue gas. Reactor feed piping is made from low-alloy steel, such as 5Cr-0.5Mo or 9Cr-1Mo, to control high-temperature sulfidic corrosion.

The main fractionation tower is usually made of carbon steel, with the lower part lined with stainless steel containing 12% Cr, such as type 405 (S40500) (Ref 91). Slurry piping between the bottom of the main fractionation tower and the reactor may receive an additional corrosion allowance as protection against excessive erosion. As a rule, there are few corrosion problems in the reaction, catalyst regeneration, and fractionation sections (Ref 92).

Hydrocracking and hydrotreating units usually require alloy protection against both high-temperature sulfidic corrosion and high-temperature hydrogen attack (Ref 93, 94). Low-alloy steels may be required for corrosion control ahead of the hydrogen injection line.

The so-called McConomy curves can be used to predict the relative corrosivity of crude oils and their various fractions (Ref 95). Although this method relates corrosivity to total sulfur content, and thus does not take into account the variable effects of different sulfur compounds, it can provide reliable corrosion trends if certain corrections are applied. Plant experience has shown that the McConomy curves, as originally published, tend to predict excessively high corrosion

rates. The curves apply only to liquid hydrocarbon streams containing 0.6 wt% S (unless a correction factor for sulfur content is applied) and do not take into account the effects of vaporization and flow regime. The curves can be particularly useful, however, for predicting the effect of operational changes on known corrosion rates.

Over the years, it has been found that corrosion rates predicted by the original McConomy curves should be decreased by a factor of roughly 2.5, resulting in the modified curves shown in Fig. 1. The curves demonstrate the beneficial effects of alloying steel with chromium in order to reduce corrosion rates. Corrosion rates are roughly halved when the next higher grade of low-alloy steel (for example, 2.25 Cr-1Mo, 5Cr-0.5Mo, 7Cr-0.5Mo, or 9Cr-1Mo steel) is selected. Essentially, no corrosion occurs with stainless steels containing 12% or more chromium. Although few data are available, plant experience has shown that corrosion rates start to decrease as temperatures exceed 455 °C (850 °F). Two explanations frequently offered for this phenomenon are the possible decomposition of reactive sulfur compounds and the formation of a protective coke layer.

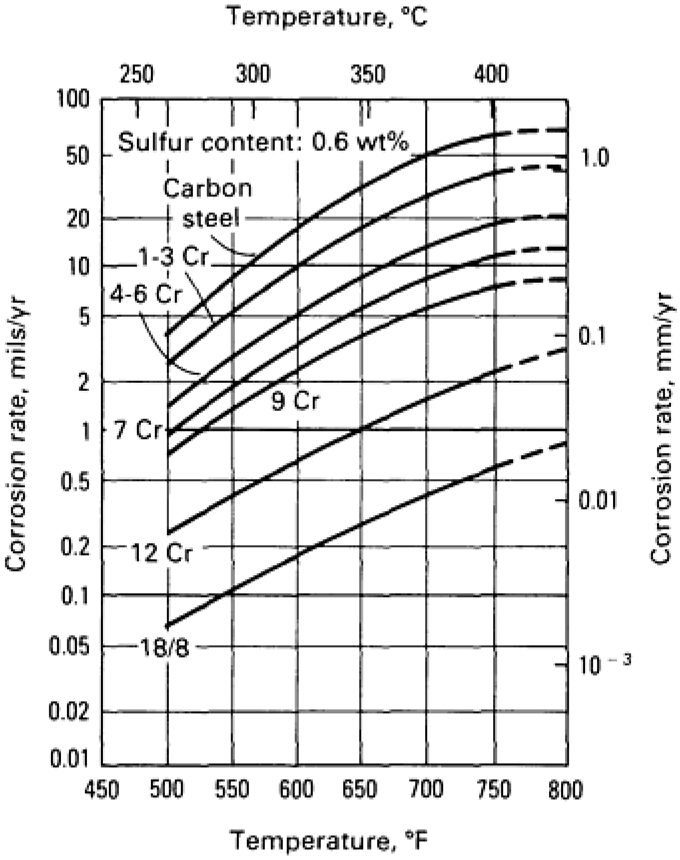

Fig. 1 Modified McConomy curves showing the effect of temperature on high-temperature sulfidic corrosion of various steels and stainless steels. Source: Ref 96

Metal skin temperatures, rather than stream temperatures, should be used to predict corrosion rates when significant differences between the two arise. For example, metal temperatures of furnace tubes are typically 85 to 110 °C (150 to 200 °F) higher than the temperature of the hydrocarbon stream passing through the tubes. Furnace tubes normally corrode at a higher rate on the hot side (fire side) than on the cool side (wall side), as shown in Fig. 2. Convective-section tubes often show accelerated corrosion at contact areas with tube hangers because of locally increased temperatures. Similarly, replacement of bare convective-section tubes with finned or studded tubes can further increase tube metal temperatures by 85 to 110 °C (150 to 200 °F).

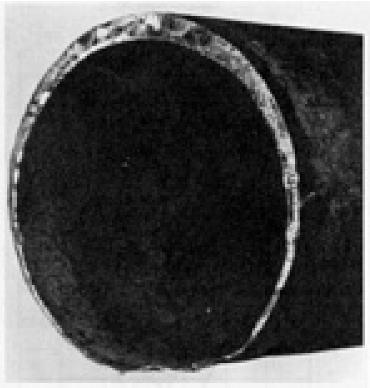

Fig. 2 High-temperature sulfidic corrosion of 150-mm (6-in.) diam carbon steel tube from radiant section of crude preheat furnace at crude distillation unit. Note accelerated attack on fire side

Correction factors for process streams with various total sulfur contents, averages of those proposed originally by McConomy, are shown in Fig. 3. As can be seen, doubling the sulfur content can increase corrosion rates by approximately 30%. To allow for the fact that the proportion of noncorrosive thiophenes is greater in high-boiling cuts (and residuum) than in the original crude charge, a corrosion factor ranging from 0.5 to 1 may have to be applied to the total sulfur content so that realistic corrosion rates can be obtained for such cuts. The degree of vaporization and the resultant two-phase flow regimes can have a significant effect on high-temperature sulfidic corrosion.

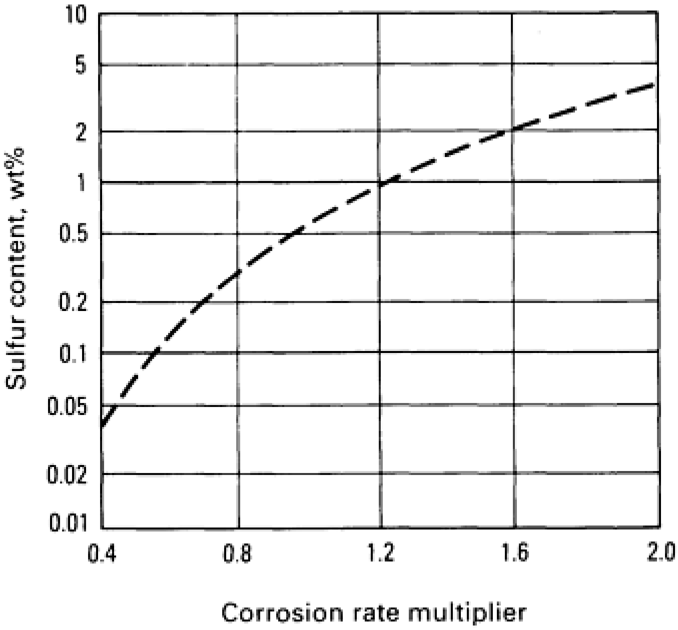

Fig. 3 Effect of sulfur content on corrosion rates predicted by modified McConomy curves in 290- to 400- °C (550- to 750- °F) temperature range. Source: Ref 96

Sulfidic Corrosion With Hydrogen Present. The presence of hydrogen in, for example, hydrotreating and hydrocracking operations, increases the severity of high-temperature sulfidic corrosion. Hydrogen converts organic sulfur compounds in feed stocks to hydrogen sulfide; corrosion becomes a function of hydrogen sulfide concentration (or partial pressure).

Downstream of the hydrogen injection line, low-alloy steel piping usually requires aluminizing in order to minimize sulfidic corrosion. Alternatively, type 321 (S32100) stainless steel can be used. Tubes in the preheat furnace are

aluminized low-alloy steel, aluminized 12% Cr stainless steel, or type 321 (S32100) stainless steel. Reactors are usually made of 2.25Cr-1Mo steel, either with a type 347 (S34700) stainless steel weld overlay or an internal refractory lining. Reactor internals are often type 321 (S32100) stainless steel (Ref 97).

Depending on the expected corrosion rates, reactor effluent piping operating above approximately 260 °C (500 °F) is made of type 321 (S32100) stainless steel, aluminized low-alloy steel, regular low-alloy steel, or carbon steel with suitable corrosion allowances. When selecting materials for this service, the recommendations of the American Petroleum Institute (API) should be followed to avoid problems with high-temperature hydrogen attack (Ref 98). The same considerations generally apply to separator drums and heat-exchanger vessels operating at temperatures above 260 °C (500 °F). Type 321 (S32100) stainless steel is usually required for heat-exchanger tubes at these temperatures.

A number of researchers have proposed various corrosion rate correlations for high-temperature sulfidic corrosion in the presence of hydrogen (Ref 99-105), but the most practical correlations seem to be the so-called Couper-Gorman curves. The Couper-Gorman curves are based on a survey conducted by National Association of Corrosion Engineers (NACE) Committee T-8 on Refining Industry Corrosion (Ref 106).

The Couper-Gorman curves differ from those previously published in that they reflect the influence of temperature on corrosion rates throughout a whole range of hydrogen sulfide concentrations. Total pressure was found not to be a significant variable between 1 and 18 MPa (150 and 2650 psig). It was also found that essentially no corrosion occurs at low hydrogen sulfide concentrations and temperatures above 315 °C (600 °F) because formation of iron sulfide becomes thermodynamically impossible. Curves are available for carbon steel, 5Cr-0.5Mo steel, 9Cr-1Mo steel, 12% Cr stainless steel, and 18Cr-8Ni austenitic stainless steel. For the low-alloy steels, two sets of curves apply, depending on whether the hydrocarbon stream is naphtha or gas oil. The curves again demonstrate the beneficial effects of alloying steel with chromium to reduce the corrosion rate.

Modified Couper-Gorman curves are shown in Fig. 4 to 11. To facilitate use of these curves, original segments of the curves were extended (dashed lines). In contrast to sulfidic corrosion in the absence of hydrogen, there is often no real improvement in corrosion resistance unless chromium content exceeds 5%. Therefore, the curves for 5Cr-0.5Mo steel also apply to carbon steel and low-alloy steels containing less than 5% Cr. Stainless steels containing at least 18% Cr are often required for essentially complete immunity to corrosion. Because the Couper-Gorman curves are primarily based on corrosion rate data for an all-vapor system, partial condensation can be expected to increase corrosion rates because of droplet impingement.

When selecting steels for resistance to high-temperature sulfidic corrosion in the presence of hydrogen, the possibility of high-temperature hydrogen attack should be considered. Conceivably, this problem arises when carbon steel and low-alloy steels containing less than 1% Cr are chosen for temperatures exceeding 260 °C (500 °F) and hydrogen partial pressures above 689 kPa (100 psia) and when corrosion rates are expected to be relatively low.

Naphthenic Acids. Naphthenic acids are organic acids that are present in many crude oils, especially those from California, Venezuela, Eastern Europe, and Russia. Although minor amounts of other organic acids can also be present, the main acids from naphthenic-base crudes are saturated ring structures with a single carboxyl group. Their general formula may be written as $R(CH_2)_nCOOH$, where R is usually a cyclopentane ring. The higher molecular weight acids can be bicyclic ($12 < n < 20$), tricyclic ($n > 20$), and even polycyclic (Ref 107, 108). Naphthenic acid content is generally expressed in terms of the neutralization number (total-acid number), which is determined by titration with potassium hydroxide, as described in ASTM D 664 (Ref 109).

Naphthenic acids are corrosive only at temperatures above approximately 230 °C (450 °F) in the 1 to 6 neutralization number range encountered with crude oil and various sidecuts. At any given temperature, corrosion rate is proportional to neutralization number. Corrosion rate triples with each 55-°C (100-°F) increase in temperature. In contrast to high-temperature sulfidic corrosion, no protective scale is formed, and low-alloy and stainless steels containing up to 12% Cr provide no benefits whatsoever over carbon steel (Ref 110). The presence of naphthenic acids may accelerate high-temperature sulfidic corrosion that occurs at furnace headers, elbows, and tees of crude distillation units because of unfavorable flow conditions.

Severe naphthenic acid corrosion has been experienced primarily in the vacuum towers of crude distillation units in the temperature zone of 290 to 345 °C (550 to 650 °F) and sometimes as low as 230 °C (450 °F) (Ref 111). Damage is in the

form of pitting and localized (lake-type) attack of tray components and vessel walls. Attack is often limited to the undersides of tray floors and to the inside and very top of the outside surfaces of bubble caps, as shown in Fig. 12. These areas are normally not covered by a layer of liquid, which suggests that the attack was caused by impinging droplets of the condensing acids. No corrosion damage is found at temperatures above 345 °C (650 °F), probably because a protective coke layer is formed.

Fig. 12 Naphthenic acid corrosion on top of 150-mm (6-in.) bubble caps made from type 317 (S31700) stainless steel containing 2.95% Mo. Tray temperature was 305 °C (580 °F)

Naphthenic acid corrosion is most easily controlled by blending crude oils having high neutralization numbers with other crude oils. Blending is designed to reduce the naphthenic acid content of the worst sidecut. In practice, blending means that the charge to the crude distillation unit has a neutralization number no higher than 0.5 to 1.0. However, this does not prevent corrosion of vacuum tower internals operating in the 290- to 345-°C (550- to 650-°F) range. These should be made from type 316 (S31600) or, preferably, type 317 (S31700) stainless steel containing at least 3.5% Mo. The vacuum tower lining in this temperature range should also be type 317 (S31700) stainless steel. Aluminum has excellent resistance to naphthenic acid corrosion in vacuum towers and can be used if its strength limitations and low resistance to velocity effects are kept in mind. Alloy 20 (N08020) and titanium grade 2 (R50400) are also resistant to naphthenic acid corrosion. In contrast, aluminized carbon steel tray components, such as bubble caps, have performed poorly.

Fuel Ash. Corrosion by fuel ash deposits can be one of the most serious operating problems with boiler and preheat furnaces. All fuels except natural gas contain certain inorganic contaminants that leave the furnace with products of combustion. These will deposit on heat-receiving surfaces, such as superheater tubes, and after melting can cause severe liquid-phase corrosion. Contaminants of this type include various combinations of vanadium, sulfur, and sodium compounds (Ref 112, 113, 114). Fuel ash corrosion is most likely to occur when residual fuel oil (Bunker C fuel) is burned.

In particular, vanadium pentoxide vapor (V_2O_5) reacts with sodium sulfate (Na_2SO_4) to form sodium vanadate ($Na_2O \cdot 6V_2O_5$). The latter compound reacts with steel, forming a molten slag that runs off and exposes fresh metal to attack. The cathodic part of the corrosion reaction is reduction of the pentoxide to the tetroxide (V_2O_4); therefore, the most common ingredient of superheater deposits is sodium vanadyl vanadate ($Na_2O \cdot V_2O_4 \cdot 5V_2O_5$). Table 7 lists the ash fusion temperatures of a number of fuel ash ingredients that can contribute to corrosion and fouling in boiler and preheat furnaces.

Table 7 Ash fusion temperatures of slag-forming compounds

Chemical compound	Chemical formula	Ash fusion temperature	
		°C	°F
Vanadium pentoxide	V_2O_5	690	1274
Sodium sulfate	Na_2SO_4	890	1630
Nickel sulfate	$NiSO_4$	840	1545
Sodium metavanadate	$Na_2O \cdot V_2O_5$	630	1165
Sodium pyrovanadate	$2Na_2O \cdot V_2O_5$	655	1210
Sodium orthovanadate	$3Na_2O \cdot V_2O_5$	865	1590
Nickel orthovanadate	$3NiO \cdot V_2O_5$	900	1650
Sodium vanadyl vanadate	$Na_2O \cdot V_2O_4 \cdot 5V_2O_5$	625	1155
Sodium iron trisulfate	$2Na_3Fe[SO_4]_3$	620	1150

Corrosion increases sharply with increasing temperature and vanadium content of fuel. If the vanadium content in the fuel oil exceeds 150 ppm, the maximum tube wall temperature should be limited to 650 °C (1200 °F). Between 20 and 150 ppm V, maximum tube wall temperatures can be between 650 and 845 °C (1200 and 1550 °F), depending on sulfur content and the sodium-vanadium ratio of the fuel oil. With 5 to 20 ppm V, the maximum tube wall temperature can exceed 845 °C (1550 °F).

In general, most alloys are likely to suffer from fuel ash corrosion. However, alloys with high chromium and nickel contents provide the best resistance to this type of attack. Sodium vanadate corrosion can be reduced by firing boilers with low excess air (<1%). This minimizes formation of sulfur trioxide in the firebox and produces high-melting slags containing vanadium tetroxide and trioxide rather than pentoxide. In the temperature range of 400 to 480 °C (750 to 900 °F), boiler tubes are corroded by alkali pyrosulfates such as sodium pyrosulfate and potassium pyrosulfate, when appreciable concentrations of sulfur trioxide are present.

Additives can be helpful in controlling corrosion, particularly in conjunction with firing with low excess air. The effectiveness of the additives varies. The most useful additives are based on organic magnesium compounds. Additives raise the melting point of fuel ash deposits and prevent the formation of sticky and highly corrosive films. Instead, a porous and fluffy deposit layer is formed with additives that can be readily removed by periodic cleaning. Magnesium-type additives offer additional benefits with regard to cold-end corrosion in boilers. Sulfuric acid condenses at temperatures between 150 and 175 °C (300 and 350 °F), depending on sulfur content of the fuel oil, and can cause serious corrosion problems. Additives neutralize any free acid by forming magnesium sulfate.

Oxidation. Carbon steels, low-alloy steels, and stainless steels react at elevated temperatures with oxygen in the surrounding air and become scaled. Nickel alloys can also become oxidized, especially if spalling of scale occurs. The oxidation of copper alloys is usually not a problem, because these are rarely used where operating temperatures exceed 260 °C (500 °F). Alloying with both chromium and nickel increases scaling resistance. Stainless steels or nickel alloys, except alloy 400 (N04400), are required to provide satisfactory oxidation resistance at temperatures above 705 °C (1300 °F). Thermal cycling, applied stresses, moisture, and sulfur-bearing gases will decrease scaling resistance. In refineries and petrochemical plants, high-temperature oxidation is primarily limited to the outside surfaces of furnace tubes, tube hangers, and other internal furnace components that are exposed to combustion gases containing excess air.

At elevated temperatures, steam decomposes at metal surfaces to hydrogen and oxygen and may cause steam oxidation of steel, which is somewhat more severe than air oxidation at the same temperature. Fluctuating steam temperatures tend to increase the rate of oxidation by causing scale to spall and thus expose fresh metal to further attack.

SCC and Embrittlement

Stress-corrosion cracking and environmental embrittlement are the most insidious forms of failure that can be experienced by process equipment, because they tend to strike without warning. Usually, there is no noticeable yielding or bulging of the component, there is no measurable metal loss, and through-thickness cracks can form in as little as 1 to 2 h after initial exposure to a crack-inducing environment. For example, cracking throughout an entire furnace coil occurred within 1 h after exposure to air and the resultant formation of polythionic acids. Towers and heat exchangers had to be scrapped because of hydrogen blistering, embrittlement, and stress cracking at welds. High-temperature hydrogen attack has

resulted in the sudden rupture of pressure vessels. With consequences such as these, the possibility and/or probability of SCC and embrittlement occurring in a given environment cannot be taken too lightly.

Stress-Corrosion Cracking

Stress-corrosion cracking that results from exposure to five different environments is summarized below. These environments are:

- Chlorides
- Caustic
- Ammonia
- Amines
- Polythionic acid

Information on the mechanisms of SCC can be found in the article "Stress-Corrosion Cracking" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*. A detailed review of tests for determining susceptibility to SCC can be found in the article "Evaluating Stress-Corrosion Cracking" also in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook.*

Chloride Cracking. Chlorides are perhaps the most common cause of SCC of austenitic stainless steels and nickel-alloys. The literature abounds with studies of the mechanism of cracking, specific environments that accelerate cracking, and tests for predicting cracking tendency. In theory, one would need only a single chloride ion in water, with sufficient oxygen and residual stresses present, to cause cracking. In practice, however, the permissible limits on chloride ion content are higher.

The usual failure mode of chloride SCC in austenitic stainless steels is the transgranular, highly branched cracking illustrated in Fig. 13. Intergranular cracking is sometimes associated with transgranular cracking, but this is not at all common. If it occurs, it is usually because of a sensitized microstructure.

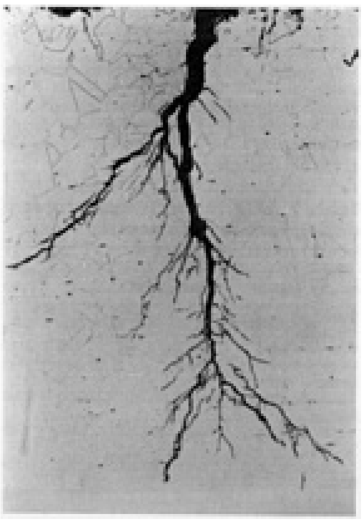

Fig. 13 Chloride SCC of type 304 (S30400) stainless steel tube by chloride-containing sour water. 70×

Based on laboratory tests in boiling 42% magnesium chloride solution, austenitic stainless steel and nickel alloys are subject to chloride SCC if their nickel content is less than about 45%. The heat treatment of an alloy was found to have no effect on its resistance to chloride SCC. In practice, however, stainless steel and nickel alloys containing greater than 30% Ni will be immune to chloride SCC in most refinery environments.

Factors that influence the rate and severity of cracking are chloride content, oxygen content, temperature, stress level, and pH value of an aqueous solution. It has been established that oxygen is required for chloride cracking to occur. Refinery and petrochemical plant experience confirms that stainless steel components, such as heat-exchanger tube bundles, usually do not crack until removed from operation and exposed to air during a shutdown. Increased oxygen content decreases the critical chloride content for cracking to occur, as shown in Fig. 14.

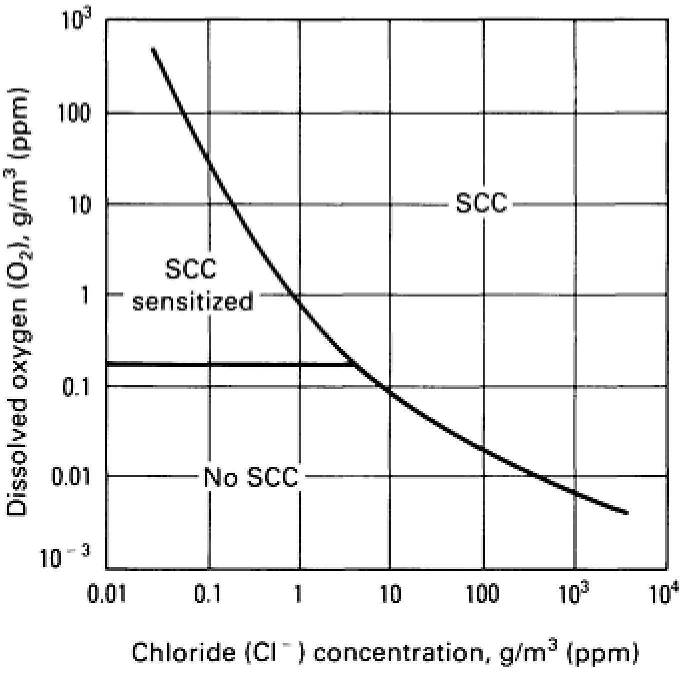

Fig. 14 Synergistic effect of chlorides and oxygen on the SCC of type 304 (S30400) stainless steel. The tests were conducted at 250 to 300 °C (480 to 570 °F) at a strain rate of <10^{-5} · s^{-1}. Source: Ref 115

The severity of cracking increases with temperature. Cracking of austenitic stainless steel components rarely occurs at ambient temperatures. Stainless steel pump impellers in seawater service have shown no cracking problems despite the fact that both chloride and oxygen contents are high. Cracking has been found to occur, however, at tropical locations where exposure to direct sunlight can increase metal temperatures significantly above ambient. As a general rule, chloride SCC of process equipment occurs only at temperatures above about 65 °C (145 °F).

The stresses required to produce cracking can be assumed to be always present. Residual stresses from forming, bending, or joining operations are sufficient for cracks to form. Thermal stress relief treatments at 870 °C (1600 °F) can effectively prevent cracking if done correctly and without the necessity of subsequent cold working (to correct distortion, for example).

In alkaline solutions, the likelihood of chloride SCC is greatly reduced. Consequently, austenitic stainless steels are frequently used for equipment exposed to amine solutions in gas-treating and sulfur recovery units. A survey of plant experiences has shown no reported instances of cracking despite the fact that chloride contents as high as 1000 ppm were measured in the circulating amine solution.

Most cracking problems occur when unexpected chlorine concentrations are found in process streams or in the atmospheric environment. For example, chloride SCC was caused by seawater spray carried by prevailing winds. The spray soaked the insulation over type 304 stainless steel, chlorides were concentrated by evaporation, and cracking occurred at areas with residual weld stresses. Other frequent causes of cracking are water dripping on warm pipe and water leaching chlorides from insulation.

As discussed previously, chlorides are present in a number of refining units, including crude distillation, hydrocracking, hydrotreating, and reforming. Chlorides are also found in other units as contamination from upstream processing, or they are introduced with stripping stream, process water, or cooling water. The latter is a particular problem in petrochemical

processes that use stainless steel heat exchangers to make steam as a means of recovering waste heat. Any chloride contamination of boiler feedwater can result in chlorides concentrating on heat-exchanger tubes and can cause pitting and SCC. As a rule, austenitic stainless steels are not recommended for components in which water is likely to evaporate or condense out.

When good resistance to aqueous sulfide corrosion is required, ferritic stainless steel or duplex stainless steels can be substituted for austenitic stainless steels (Ref 116, 117). Ferritic stainless steels, such as type 405 (S40500) or type 430 (S43000), are not susceptible to chloride SCC. The duplex stainless steels have a mixed ferritic-austenitic structure and are resistant to chloride SCC, but are not immune to highly aggressive chloride environments. For example, cold-worked type 329 (S32900) stainless steel has cracked when chlorides were concentrated by vaporization of a process stream, as shown in Fig. 15. Some of the new proprietary duplex stainless steels, such as 3RE60 (S31500) and 2205 (S31803), have reportedly shown increased resistance toward chloride SCC.

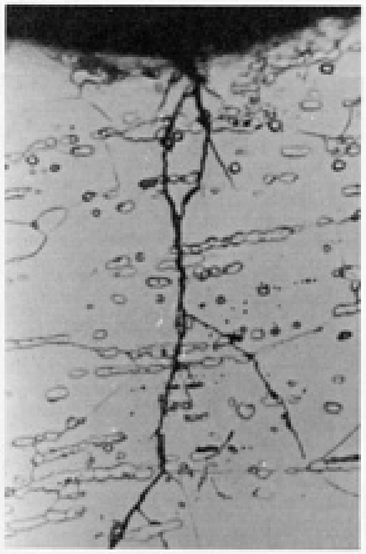

Fig. 15 Chloride SCC of type 329 (S32900) stainless steel by chloride salts that concentrated as water evaporated

There are no simple methods of preventing SCC when an austenitic stainless steel must be used in an environment known to contain chlorides. Chloride SCC in refineries and petrochemical plants often occurs under shutdown conditions when air and moisture enters equipment opened for inspection and repair. It has been found that the precautionary measures outlined in NACE RP-01-70 for the prevention of cracking by polythionic acids also help prevent cracking by chlorides (Ref 118). In particular, excluding air and moisture by nitrogen blanketing and rinsing equipment with an aqueous 0.5% sodium nitrate solution have been shown to inhibit chloride SCC. To prevent chloride SCC on the outside of insulated pipe, aluminum foil has been wrapped between the insulation and pipe to provide some measure of cathodic protection. One method of preventing the catastrophic failure of components by chloride SCC would be the use of austenitic stainless steel as an internal cladding. The highly branched mode of any cracking would effectively prevent the development of stress raisers. Carbon or low-alloy steel base metal would not be susceptible to cracking in chloride solutions, but some localized corrosion may occur. This type of construction would also provide resistance to cracking when chlorides are liable to contact the outside of the components, as in external insulation, for example.

Caustic Cracking. Stress-corrosion cracking of various steels and stainless steels by caustic (sodium hydroxide) is also fairly common in refinery and petrochemical plant operations. Caustic is added in the form of 5 to 40% aqueous solution to certain process streams in order to neutralize residual acid catalysts, such as sulfuric acid, hydrofluoric acid, and hydrochloric acid. Caustic is also added to cooling water and boiler feedwater to counteract large decreases in pH value due to process leaks.

Although caustic attack is primarily in the form of localized corrosion (gouging) in some process streams (for example, crude oil), in others it may take the form of SCC. Traces of caustic can become concentrated in boiler feedwater and cause SCC (caustic embrittlement). This occurs in boiler tubes that alternate between wet and dry conditions (steam

blanketing) because of overfiring. Locations such as cracked welds or leaky tube rolls can form steam pockets with cyclic overheating and quenching conditions. These frequently lead to caustic embrittlement.

Caustic SCC of carbon steel occurs at temperatures above 50 to 80 °C (120 to 180 °F), depending on caustic concentration. Welded carbon steel components that are exposed to caustic solutions above these temperatures should be postweld heat treated at 620 °C (1150 °F) for 1 h per 25 mm (1 in.) of metal thickness. Caustic SCC of austenitic stainless steels occurs between 105 and 205 °C (220 and 400 °F), depending on caustic concentration.

Cracking of austenitic stainless steels is often difficult to distinguish from cracking by chlorides, particularly because common grades of caustic also contain some sodium chloride. As a general rule, however, SCC by chlorides is usually, but not always, in the form of transgranular cracking, while caustic causes intergranular cracking, sometimes accompanied by transgranular cracking due to the presence of chlorides.

Caustic SCC of carbon steel is often initiated at discontinuities in areas of surface deformation as a result of cold-working or welding operations (Ref 119). Although caustic SCC occurs over a wide range of temperatures, there appears to be no correlation between temperature and time to failure. Because few failures have been reported at near-ambient temperatures, it appears that crack initiation times are inordinately long unless precracking, for example, in the form of weld defects, has occurred.

Caustic cracking of carbon steel has been found to occur over a narrow range of potentials near the active current peak of potential/log current curves. Typically, this potential range is centered about -700 mV versus the standard hydrogen electrode (SHE). The most negative (active) potential for inducing caustic cracking coincides with the potential for initiating passivation by magnetite (Fe_3O_4) formation. Cracking is promoted by small amounts of dissolved oxygen, sodium chloride, lead oxide, silica, silicates, sulfates, nitrates, permanganate, and chromates that cause the active corrosion potential to move slightly in the positive (noble) direction. In contrast, large amounts of these substances act as inhibitors by pushing the corrosion potential into the passivation range. Phosphates, acetates, carbonates, and tannins also act as inhibitors.

Ammonia Cracking. Ammonia has caused two types of SCC in refineries and petrochemical plants. The first is cracking of carbon steel in anhydrous ammonia service, and the second type is cracking of copper alloys, such as admiralty metal (C44300). In copper alloys, SCC can occur by ammonia contamination of process streams or by ammonia-base neutralizers that are added to control corrosion.

Carbon steel storage vessels, primarily spheres, have developed stress-corrosion cracks in anhydrous ammonia service at ambient temperature but elevated pressure. In most cases, cracking was detected by inspection before leakage or rupture, but there were at least two catastrophic failures (Ref 120). There have been few problems with semirefrigerated storage vessels and no documented cases of SCC in cryogenic storage vessels. The primary causes of cracking are high stresses, hard welds, and air contamination.

To minimize the likelihood of cracking, only low-strength steels, with a maximum tensile strength of 483 MPa (70 ksi), should be used in anhydrous ammonia service. Welds should be postweld heat treated at 595 °C (1100 °F) or higher, with a maximum allowable hardness of 225 HB. A water content of at least 0.2% should be maintained in the ammonia because water has been found to be an effective inhibitor of cracking. Air contamination increases the tendency toward cracking and should be minimized, if necessary, by the addition of hydrazine to the water. With a water content of 10 ppm, the oxygen content should be below 10 ppm for safe operation (Ref 121). The permissible oxygen content increases to 100 ppm with a water content of 0.1 percent. Regular inspection of all components in anhydrous ammonia service is recommended.

Cracking of admiralty metal (C44300) heat-exchanger tubes has been a recurring problem in a number of refining units and petrochemical process units. For example, ammonia is often used to neutralize acidic constituents, such as hydrogen chloride or sulfur dioxide, in overhead systems of crude distillation or alkylation units, respectively. Stripped sour water containing residual ammonia is used as desalter water at some crude distillation units. This practice causes ammonia contamination of the overhead system even if no ammonia is added intentionally. Ammonia is formed from nitrogen-containing feed stocks during catalytic cracking, hydrotreating, and hydrocracking operations. As a rule, cracking of admiralty metal (C44300) tubes occurs only during shutdowns when ammonia-containing deposits on the tube surfaces become exposed to air. To prevent cracking, tube bundles should be sprayed with a very dilute solution of sulfuric acid immediately after they are pulled from their shells in order to neutralize any residual ammonia. Cracking of admiralty metal (C44300) tubes has occasionally been attributed to traces of ammonia in cooling water.

Amine Cracking. Stress-corrosion cracking of carbon steel by aqueous amine solutions, which are used to remove hydrogen sulfide and carbon dioxide from refinery and petrochemical plant streams, has been a recurring problem for a number of years. In one case involving 20 wt% monoethanolamine solution, the affected equipment included two amine storage tanks, four absorber towers, a rich-amine flash drum, a lean-amine carbon treater, and various piping (Ref 122). Cracking was found primarily at welds exposed to amine solutions at temperatures ranging from 50 °C (125 °F) to below 95 °C (200 °F). Cracking was intergranular, with crack surfaces covered by a thin film of magnetite. No cracking was found in piping that had received postweld heat treatment and was operating at temperatures as high as 155 °C (310 °F). Consequently, most of the affected components were replaced with new ones that had received postweld heat treatment. After careful magnetic-particle inspection, the rest of the components were repaired: welds received were postweld heat treated *in situ* or were stress relieved by shot peening.

In another, more recent case, a number of leaks were discovered at piping welds in lean-amine service at temperatures between 40 and 60 °C (100 and 140 °F). None of these welds had been postweld heat treated. Again, the affected components were replaced with new ones that had received a postweld heat treatment (Ref 123). Cracking of piping welds has also occurred in lean-amine piping of several gas-treating plants, but in all cases, temperatures were well above 95 °C (200 °F). For various reasons, these welds had not been postweld heat treated. Different types of amine solutions, including monoethanolamine, diethanolamine, and sulfinol (containing diisopropanolamine), were involved; this confirms that cracking is not limited to monoethanolamine solutions.

Amine SCC appears to be a form of alkaline SCC that is similar in many ways to caustic SCC. The failure mode is intergranular cracking in otherwise ductile material, usually without the formation of visible corrosion products. Cracks, which typically run parallel to the weld, are found in the weld metal, in the base metal, (~5 mm, or 0.2 in., away from the weld), and in the HAZ. Cracking is not related to weld hardness. To prevent amine SCC, postweld heat treatment at 620 °C (1150 °F) was recommended in the past for carbon steel welds exposed to amine solutions at temperatures exceeding 95 °C (200 °F). In light of the recently reported failures, welds of carbon steel components in amine service should be postweld heat treated regardless of service temperature.

Polythionic Acid Cracking. Stress-corrosion cracking of austenitic stainless steels by polythionic acids was first identified with the introduction of hydrotreating units. Austenitic stainless steels were required to provide resistance to high-temperature sulfidic corrosion in the presence of hydrogen. It was found that unstabilized austenitic stainless steel, such as type 304 (S30400), would crack adjacent to weldments during shutdowns. Typically, cracks were found to penetrate piping with a wall thickness of 12 mm (0.5 in.) in less than 8 h. Failures have been limited mostly to furnace tubes, heat-exchanger tubes, thermowells, and vessel linings (Ref 124). Similar cracking was also found in hydrocracking units and, more recently, in catalytic cracking units, in which austenitic stainless steels have found greater use because of an increase in catalyst regeneration temperatures (Ref 125).

Examples of SCC by polythionic acids are shown in Fig. 16, 17, and 18. The cracking in roll-bonded cladding of type 304 (S30400) stainless steel (Fig. 16) is similar to mud cracking. Figure 17 shows the cracking that occurred in a type 304 (S30400) furnace tube near the weld to a carbon steel tube. These cracks are both parallel and perpendicular to the weld, reflecting different stresses in the weldment. The intergranular mode of crack propagation is shown in Fig. 18 and clearly distinguishes SCC by polythionic acids from chloride SCC (but not from caustic SCC).

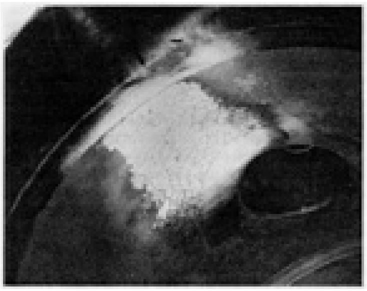

Fig. 16 Polythionic acid SCC of roll-bonded type 304 (S30400) stainless steel cladding. Note that cracking stops at the type 304 (S30400) weld overlay around the nozzle opening

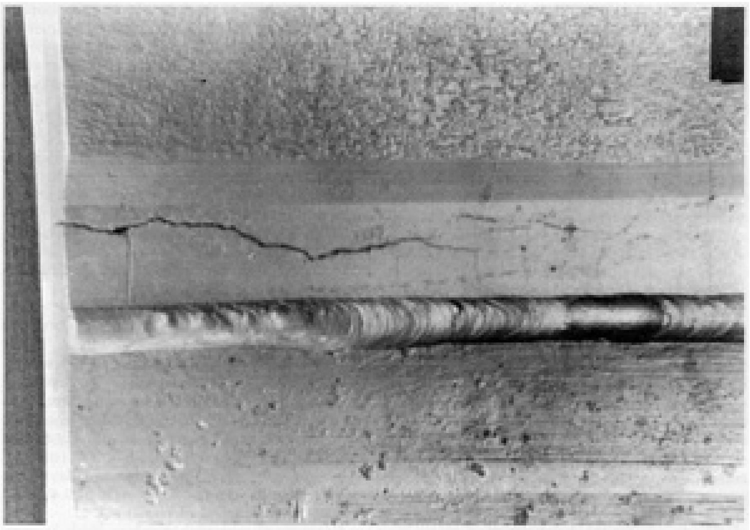

Fig. 17 Polythionic acid SCC of type 304 (S30400) furnace tube near weld to carbon steel tube. Cracking is both parallel and perpendicular to weld but not in the weld

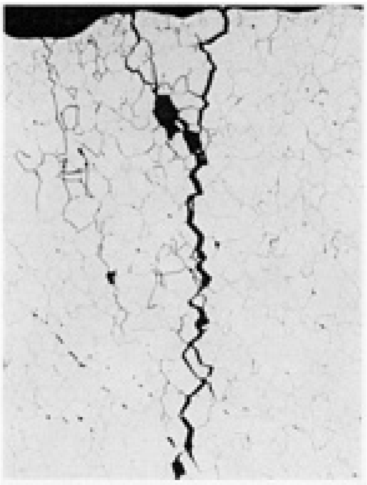

Fig. 18 Intergranular cracking typical of polythionic acid SCC in type 304 (S30400) stainless steel. 75×

Polythionic acid SCC occurs only in austenitic stainless steels and nickel-chromium-iron alloys that have become sensitized through thermal exposure (Ref 126, 127). Sensitization occurs when the carbon present in the alloy reacts with chromium to produce chromium carbides at the grain boundaries. As a result, the areas adjacent to the grain boundaries become depleted in chromium and are no longer fully resistant to certain corrosive environments.

Sensitization of type 304 (S30400) stainless steels normally occurs at temperatures between 400 and 815 °C (750 and 1500 °F), whenever the alloy is slowly cooled through this temperature range (such as during welding and heat treating), or during normal process operations. The higher the temperature, the shorter the time of exposure required for sensitization. Addition of stabilizing elements, such as titanium or niobium, or limiting the amount of carbon are two methods for reducing the effects of welding and heat treating on sensitization. However, they are not effective for long-term exposure to temperatures above 430 °C (800 °F). The resistance of titanium-stabilized type 321 (S32100) stainless steel to polythionic SCC can be significantly improved by a thermal stabilization at approximately 900 °C (1650 °F) and holding for 2 h, with no specific limits on the cooling rate. Thermal stabilization causes the precipitation of carbon as titanium carbide rather than chromium carbide and therefore decreases the amount of carbon available for chromium carbide formation upon subsequent high-temperature exposure. Also, any chromium depletion that does occur near the grain boundaries during this time period will be counteracted by chromium diffusion from within the alloy.

Laboratory studies and plant experiences have demonstrated that austenitic stainless steels are not sensitized when applied as a weld overlay over carbon or low-alloy steels. The lack of sensitization under these conditions was verified by testing stressed samples in a solution containing polythionic acids. As can be seen in Fig. 16, SCC of the roll-bonded cladding stops at the weld overlay around the nozzle.

Polythionic acids of the type $H_2S_xO_y$ (including sulfurous acid) are formed by the reaction of oxygen and water with the iron/chromium sulfide scale that covers the surfaces of austenitic stainless steel components as a result of high-temperature sulfidic corrosion. Because neither oxygen nor water is present during normal operation under conditions in which austenitic stainless steels would be used, SCC evidently occurs during shutdowns. Oxygen and water originate from steam or wash water used to free components of hydrocarbons during shutdown before inspection or simply from atmospheric exposure. In catalytic cracking units, oxygen and water can be present during normal operations at certain locations of the catalyst regeneration system because of steam purges and water sprays for preventing catalyst accumulation. The components involved include air rings, plenums, slide valves, cyclone components, and expansion joint bellows in the catalyst regenerator and associated lines.

In general, however, SCC by polythionic acids is considered to be a problem primarily during shutdown periods; suitable procedures to prevent cracking are outlined in NACE RP-01-70 (Ref 118). These procedures include nitrogen purging of components that were opened to the atmosphere, purging with dry air having a dew point below -15 °C (5 °F), or neutralizing any polythionic acids that are formed, by washing components with a 2% aqueous soda ash (sodium carbonate) solution.

Soda ash solution should also be used for hydrotesting prior to returning components to service. Residues of soda ash solution should be left on components during temporary storage to prevent SCC. The need for this can be illustrated by an experience with a U-tube heat-exchanger bundle fabricated of type 304 (S30400) stainless steel. After the bundle had been removed from a hydrotreating unit, the external surfaces of the tubes were washed with soda ash solution, which was allowed to dry. Before storing the bundle outdoors, instructions were given to cover it to prevent rainwater from washing off the soda ash residues. It was later discovered, however, that the U-bends had not been covered and that extensive SCC had taken place at these locations.

Hydrogen Damage

Corrosion of carbon and low-alloy steels by aqueous hydrogen sulfide solutions or sour waters can result in one or more types of hydrogen damage. These include loss of ductility on slow application of strain (hydrogen embrittlement), formation of blisters or internal voids (hydrogen blistering), and spontaneous cracking of high-strength or high-hardness steels (hydrogen stress cracking).

Atomic hydrogen (H) forms as part of the corrosion process and then evolves from cathodic areas of the metal as molecular hydrogen (H_2). When corrosion rates are high enough, desorption of molecular hydrogen from the surface becomes rate controlling. As the concentration of atomic hydrogen builds up at the surface, it diffuses into the steel and reduces its ductility. This embrittling effect is caused by hydrogen atoms collecting interstitially between metal atoms. The metal lattice becomes locally distorted, which restricts the mobility of dislocations and therefore the ability of the lattice to deform. Hydrogen atoms preferentially diffuse along grain boundaries and zones where the lattice has already been distorted by cold working or hardening. Atomic hydrogen can also combine to form molecular hydrogen at voids, such as manganese sulfide inclusion or laminations. Because of their larger size, hydrogen molecules cannot diffuse out of the steel, and blistering and fissuring are the result. Hydrogen stress cracking of embrittled metal is caused by static external stresses, transformation stresses (for example, as a result of welding), internal stresses, cold working, and hardening. As a rule, cracking does not occur in ductile steels or in steels that have received a proper postweld heat treatment.

Hydrogen damage occurs primarily when steel is exposed to aqueous hydrogen sulfide solutions having low pH values. Hydrogen sulfide, chemisorbed to the steel surface, partially poisons the reaction between hydrogen atoms that yields molecular hydrogen. Aqueous hydrogen sulfide solutions having high pH values can also cause hydrogen damage if cyanides are present. In the absence of cyanides, aqueous hydrogen sulfide solutions with pH values above 8 do not corrode steel, because a protective iron sulfide film forms on the surface.

Cyanides destroy this protective film and convert it into soluble ferrocyanide [$Fe(CN)_6^{-4}$] complexes. As a result, the now unprotected steel can corrode very rapidly. For practical purposes, the corrosion rate depends primarily on the bisulfide ion (HS^-) concentration and, to a lesser extent, on the cyanide ion (CN^-) concentration. The more bisulfide ion that is

present, the more cyanide that is required to destroy the protective iron sulfide film. It has been shown experimentally that corrosion of steel in aqueous ammonia/sulfide/cyanide solutions with pH values above 8 is always accompanied by hydrogen damage (Ref 54).

Hydrogen embrittlement is characterized by decreasing ductility with decreasing strain rate; this is contrary to metal behavior in most other types of embrittlement (Ref 128). For example, the ductility of carbon steel has been reported to drop from 42 to 7% when charged with hydrogen (Ref 129). This loss of ductility is only observed during slow strain rate testing and conventional tensile tests, but not during impact tests, such as the Charpy V-notch test. Failure, in the form of cracking, usually occurs some time after a load is applied to hydrogen-charged steel. Because this phenomenon is also known as static fatigue, the minimum load for failure to occur is known as the static fatigue limit.

Hydrogen embrittlement is temporary and can be reversed by heating the steel to drive out the hydrogen. The rate of recovery depends on time and temperature. Heating to 230 °C (450 °F) and holding for 1 h/25 mm (1 in.) of thickness has been found to be adequate to prevent cracking after welding. Although temperatures as high as 650 °C (1200 °F) for 2 h or as low as 105 °C (225 °F) for 1 day have reportedly been used to restore full ductility, even the heat of the sun on a summer day was found to be sufficient to restore ductility to a high-carbon cold-drawn steel wire that had been embrittled by exposure to wet hydrogen sulfide. As a rule, however, heating to temperatures above 315 °C (600 °F) for any length of time should be avoided to lessen the possibility of high-temperature hydrogen attack.

Titanium can also become embrittled by absorbed hydrogen as a result of corrosion or exposure to dry hydrogen gas (Ref 20). When hydrogen is absorbed by titanium in excess of about 150 ppm, a brittle titanium hydride phase will precipitate out, as shown in Fig. 19. Embrittlement due to titanium hydride precipitation is usually permanent and can be reversed only by vacuum annealing, which is difficult to perform. Absorption of hydrogen by titanium dramatically increases once the protective oxide film normally present on the metal is damaged through either mechanical abrasion or chemical reduction. Hydrogen intake is accelerated by the presence of surface contaminants, including iron smears, and occurs predominantly as temperatures exceed 70 °C (160 °F).

Fig. 19 Hydride formation in titanium grade 2 (R50400) after galvanic coupling to carbon steel in sour water at 110 °C (230 °F)

Hydriding can be minimized by anodizing or thermal oxidizing treatments to increase the thickness of the protective oxide film. If it is impractical to apply these treatments, acid pickling of titanium components--with 10 to 30 vol% nitric acid containing 1 to 3 vol% hydrofluoric acid at 49 to 52 °C (120 to 125 °F) for 1 to 5 min--can be performed to remove iron smears. Acid pickling is also recommended for cleaning titanium components after inspection and repairs during shutdowns, especially components exposed to concentrated acetic acid in certain petrochemical operations. To minimize hydrogen pickup during pickling, the volume ratio of nitric acid to hydrofluoric acid should be near 10. In some highly aggressive process environments, titanium components may have to be electrically insulated from more anodic components, such as aluminum, to prevent hydride formation as a result of hydrogen evolution on titanium surfaces. When process streams contain a significant volume of hydrogen (for example, reactor effluent from hydrotreating units), titanium should be used only at temperatures below 175 °C (350 °F).

Information on the mechanism of hydrogen embrittlement is available in the article "Hydrogen Damage" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*. Test procedures are reviewed in the article "Evaluating Hydrogen Embrittlement", also in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Hydrogen blistering has been a problem primarily in the vapor recovery (light ends) section of catalytic cracking units and, to a lesser degree, in the low-temperature areas of the reactor effluent section of hydrotreating and hydrocracking units (Ref 130, 131, 132). Hydrogen blistering has also been seen in the overhead systems for sour water stripper towers and amine regenerator (stripper) towers, as well as in the bottom of amine contactor (absorber) towers.

An example of hydrogen blistering in an absorber/stripper tower of a catalytic cracking unit is shown in Fig. 20. Hydrogen blistering often accompanies hydrogen embrittlement as a result of aqueous sulfide corrosion. Internal hydrogen blistering on a microscopic scale along grain boundaries (fissures) can lead to hydrogen-induced stepwise cracking. Cracking proceeds as metal ligaments between adjacent fissures crack because of applied stresses. As a rule, the severity of hydrogen blistering depends on the severity of corrosion, but even low corrosion rates can produce enough hydrogen to cause extensive damage. In some cases, hydrogen blistering is limited to dirty steel with highly oriented slag inclusions or laminations. Vapor/liquid interface areas in equipment often show most of the damage, probably because ammonia, hydrogen sulfide, and hydrogen cyanide concentrate in the thin water films or in water droplets that collect at these areas.

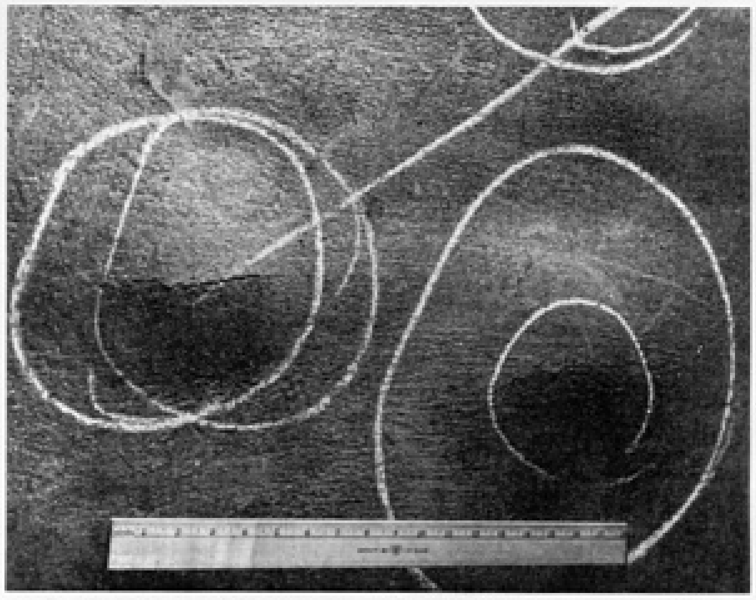

Fig. 20 Hydrogen blistering of a carbon steel shell of an absorber/stripper tower in the vapor recovery (light ends) section of a catalytic cracking unit. Note that the blisters have cracked open to the vessel interior

The basic approach toward reducing corrosion and hydrogen blistering in the various vapor-compression stages of catalytic cracking units should be aimed at decreasing the concentration of cyanide and bisulfide ions in water condensate. Several methods for accomplishing this have been tried over the years (Ref 133, 134). Conversion of cyanide to harmless thiocyanate (SCN^-) by injection of air or polysulfide solutions at various locations has often produced undesirable side effects, such as accelerated corrosion and fouling at stagnant-flow areas. In contrast, water washing of the compressed wet-gas streams, in conjunction with corrosion inhibitor injection, has been found to be very effective when applied correctly and consistently (Ref 135). Water washing reduces the concentration of cyanides by improved contacting of vapors and dilution of water condensate. To prevent dissolved and suspended solids from fouling the compressor aftercooler, only water of fairly good quality, such as boiler feedwater or steam condensate, should be injected. To reduce the amount of freshwater used, stripping-stream condensate from the reflux drum can be used. As a rule, there is sufficient stripping-steam condensate to meet the wash-water requirements.

It is important that the waste sour water from the interstage and high-pressure separator drums be sent directly to waste disposal rather than first being recycled to the reflux drum. Waste water is often recycled for convenience so that its

pressure can be reduced in the reflux drum prior to disposal. This alleviates the need for an external depressuring drum, but will build up the concentration of ammonia, hydrogen sulfide, and, especially, hydrogen cyanide in the wet gas leaving the reflux drum. Consequently, excessive concentrations of cyanides will be found in water condensing in the high-pressure stage. Water washing of the overhead of the debutanizer and depropanizer is indicated only if serious fouling problems occur. Normally, these streams are quite dry and should be kept that way to minimize corrosion and hydrogen blistering problems. With proper water washing of the compressed wet-gas stream, water washing of the overhead vapor streams of the debutanizer and depropanizer towers becomes unnecessary.

Corrosion inhibitors help control aqueous sulfide corrosion and hydrogen blistering even though cyanides may still be present. Hydrogen activity probes and chemical tests of water condensate are used to monitor the effectiveness of water washing and inhibitor injection. Where limited hydrogen blistering occurs in certain components of hydrotreating and hydrocracking units, it is usually sufficient to line affected areas with stainless steel or alloy 400 (N04400). This also applies to components of overhead systems for sour water stripper towers and amine regenerator (stripper) towers or the bottoms of amine contactor (absorber) towers.

Hydrogen Stress Cracking. Sour water containing hydrogen sulfide can cause spontaneous cracking of highly stressed high-strength steel components, such as bolting and compressor rotors (Ref 136). Cracking has also occurred in carbon steel components containing hard welds (Ref 137). Cracking is typically transgranular and will contain sulfide corrosion products, as shown in Fig. 21 and 22. Cracking of this type has become known as hydrogen stress cracking or sulfide cracking and should not be confused with hydrogen-induced stepwise cracking.

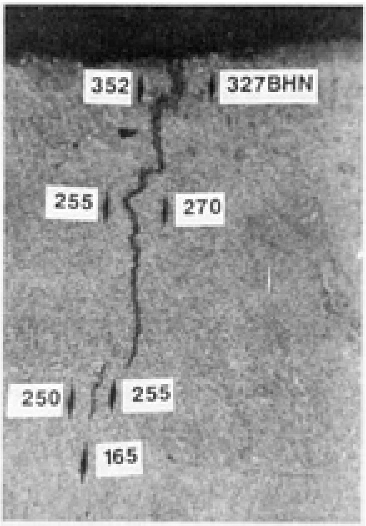

Fig. 21 Hydrogen stress cracking of a hard weld of a carbon steel vessel in sour water service. BHN = Brinell hardness. 40×

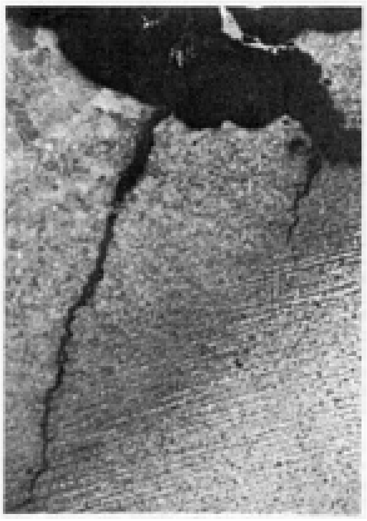

Fig. 22 Hydrogen stress cracking of hard HAZ next to weld in A516-70 pressure vessel steel after exposure to sour water. 35×

Hydrogen stress cracking was first identified in the production of sour crude oils when high-strength steels used for well-head and down-hole equipment cracked readily after contacting produced water that contained hydrogen sulfide. Hydrogen stress cracking was not experienced by refineries and petrochemical plants until the introduction of high-pressure processes that required high-strength bolting and other components in gas compressors. With the increased use of submerged arc welding for pressure vessel construction it was found that weld deposits significantly harder and stronger than the base metal could be produced. This led to transverse cracking in the weld deposit.

The mechanism of hydrogen stress cracking has been the subject of many investigations, most of which attempted to address the cracking seen in high-strength steels instead of the lower-strength steels used in refinery and petrochemical plant equipment. In general terms, hydrogen stress cracking occurs in the same corrosive environments that lead to hydrogen embrittlement. Hydrogen sulfide affects the corrosion rate and the relative amount of hydrogen absorption, but otherwise does not appear to be directly involved in the cracking mechanism. As a general rule of thumb, hydrogen stress cracking can be expected to occur in process streams containing in excess of 50 ppm hydrogen sulfide (although cracking has been found to occur at lower concentrations).

There is a direct relationship between hydrogen sulfide concentration and the allowable maximum hardness value of the HAZ on one hand and cracking threshold stress on the other. Typically, the allowable maximum hardness value decreases 30 HB, and the allowable threshold stress decreases by 50% for a tenfold increase in hydrogen sulfide concentration (Ref 138). Also, hydrogen stress cracking occurs primarily at ambient temperature. As in the case of hydrogen embrittlement and hydrogen blistering, hydrogen stress cracking of steel in refineries and petrochemical plants often requires the presence of cyanides.

The most effective way of preventing hydrogen stress cracking is to ensure that the steel is in the proper metallurgical condition. This means that weld hardness is limited to 200 HB (Ref 139). Because hard zones can also form in the HAZs of welds and shell plates from hot forming, the same hardness limitation should be applied in these areas. Guidelines for dealing with the hydrogen stress cracking that occurs in refineries and petrochemical plants are given in API 942 (Ref 140) and NACE RP-04-72 (Ref 141).

Postweld heat treatment of fabricated equipment will greatly reduce the occurrence of hydrogen stress cracking. The effect is twofold: First, there is the tempering effect of heating to 620 °C (1150 °F) on any hard microstructure, and second, the residual stresses from welding or forming are reduced. The residual stresses represent a much larger strain on the equipment than internal pressure stresses.

A large number of the ferrous alloys, including the stainless steels, as well as certain nonferrous alloys, are susceptible to hydrogen stress cracking. Cracking may be expected to occur with carbon and low-alloy steels when the tensile strength exceeds 620 MPa (90 ksi). Because there is a relationship between hardness and strength in steels, the above strength

level approximates the 200 HB hardness limit. For other ferrous and nonferrous alloys used primarily in oil field equipment, limits on hardness and/or heat treatment have been established in NACE MR-01-75 (Ref 142). Although oil field environments can be more severe than those encountered during refining, the recommendations can be used as a general guide for material selection.

Hydrogen Attack

The term hydrogen attack (or, more specifically, high-temperature hydrogen attack) refers to the deterioration of the mechanical properties of steels in the presence of hydrogen gas at elevated temperatures and pressures. Although not a corrosion phenomenon in the usual sense, hydrogen attack is potentially a very serious problem with regard to the design and operation of refinery equipment in hydrogen service (Ref 143, 144). It is of particular concern in hydrotreating, reforming, and hydrocracking units at above roughly 260 °C (500 °F) and hydrogen partial pressures above 689 KPa (100 psia) (Ref 145). Under these conditions, molecular hydrogen (H_2) dissociates at the steel surface to atomic hydrogen (H), which readily diffuses into the steel. At grain boundaries, dislocations, inclusions, gross discontinuities, laminations, and other internal voids, atomic hydrogen will react with dissolved carbon and with metal carbides to form methane. The large size of its molecule precludes methane diffusion. As a result, internal methane pressures become high enough to blister the steel or to cause intergranular fissuring (Ref 131). If temperatures are high enough, dissolved carbon diffuses to the steel surface and combines with atomic hydrogen to evolve methane. Hydrogen attack now takes the form of overall decarburization rather than blistering or cracking.

The overall effect of hydrogen attack is the partial depletion of carbon in pearlite (decarburization) and the formation of fissures in the metal, as shown in Fig. 23. As attack proceeds, these effects become more pronounced, as shown in Fig. 24, in which partial depletion of carbon is evident in some of the grains while others are completely decarburized. Hydrogen attack is accompanied by loss of tensile strength and ductility. Consequently, unexpected failure of equipment without prior warning signs is the primary cause for concern.

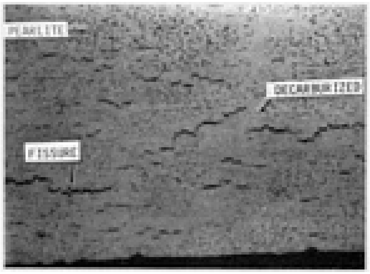

Fig. 23 High-temperature hydrogen attack of carbon steel in the form of decarburization and fissuring. 50×

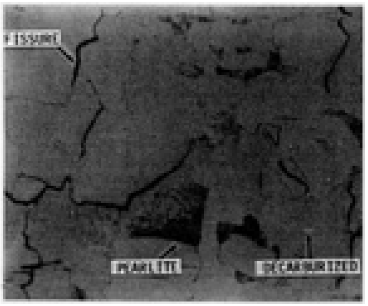

Fig. 24 Depletion of carbon in pearlite colonies and formation of grain-boundary fissures due to high-temperature hydrogen attack of carbon steel. 140×

Forms of Hydrogen Attack. Hydrogen attack can take several forms within the metal structure, depending on the severity of the attack, stress, and the presence of inclusions in the steel. The following discussion will illustrate these. General surface attack occurs when equipment, which is not under stress, is exposed to hydrogen at elevated temperatures

and pressures. As a rule, decarburization is not uniform across the surface or through the thickness; instead, it takes place at various locations within the structure. The fissures that form are parallel to the metal surface. The fissures themselves are small and are not linked together, as may happen with more severe stages of attack.

Hydrogen attack often initiates at areas of high stress or stress concentration in the steel because atomic hydrogen preferentially diffuses to these areas. Isolated fingers of decarburized and fissured material are often found adjacent to weldments and are associated with the initial stages of hydrogen attack. It is also evident that the fissures tend to be parallel to the edge of the weld rather than the surface. This orientation of fissures is probably the result of residual stress adjacent to the weldment. Fissures in this direction can form through-thickness cracks.

The necessary stress for inducing localized hydrogen attack is not limited to weldments. Hydrogen attack has been found to be concentrated at the tip of a fatigue crack that initiated at the toe of a fillet weld and propagated along the HAZ of the weld. In this case, the hydrogen-containing process stream evidently entered the fatigue crack and caused fissuring around the crack tip, as shown in Fig. 25. Although no evidence of attack was found in adjacent portions of the piping system, the localized attack was the cause of a major failure.

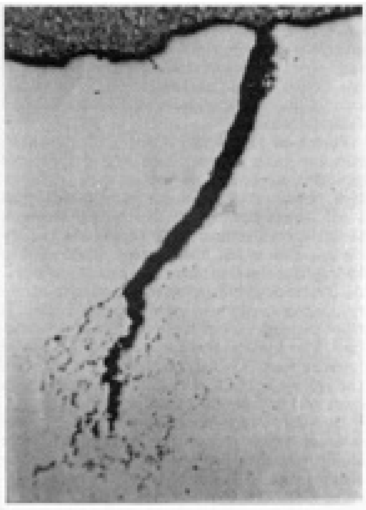

Fig. 25 High-temperature hydrogen attack, in the form of localized fissuring, at the tip of a fatigue crack that initiated at the toe of a fillet weld. 70×

Severe hydrogen attack can result in blisters and laminations, as shown in Fig. 26. This is an advanced stage of hydrogen attack, and it is accompanied by complete decarburization throughout the cross section of the steel. The laminar nature of the fissures is typically obtained when no local stresses are present, but the physical appearance of this blistering is quite similar to hydrogen blistering (described earlier).

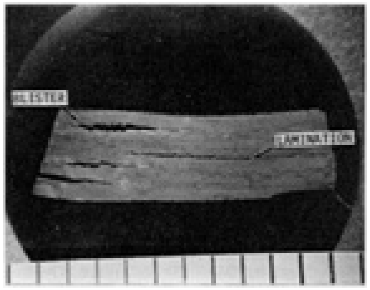

Fig. 26 High-temperature hydrogen attack in the form of blistering and laminar fissuring throughout the wall thickness of a carbon steel pipe

Prevention of Hydrogen Attack. The only practical way to prevent hydrogen attack is to use only steels that, based on plant experience, have been found to be resistant to this type of deterioration. The following general rules are applicable to hydrogen attack:

- Carbide-forming alloying elements, such as chromium and molybdenum, increase the resistance of steel to hydrogen attack
- Increased carbon content decreases the resistance of steel to hydrogen attack
- Heat-affected zones are more susceptible to hydrogen attack than the base or weld metal

For most refinery and petrochemical plant applications, low-alloy chromium- and molybdenum-containing steels are used to prevent hydrogen attack. However, questions have recently been raised regarding the effect of long-term hydrogen exposure on C-0.5Mo steel (Ref 146). As a result, low-alloy steels are preferred over C-0.5Mo steel for new construction.

The conditions under which different steels can be used in high-temperature hydrogen service are listed in API 941 (Ref 147). The principal data are presented in the form of Nelson curves, as shown in Fig. 27. The curves are based on long-term refinery experience, rather than on laboratory studies. The curves are periodically revised by the API Subcommittee on Materials Engineering and Inspection, and the latest edition of API 941 should be consulted to ensure that the proper steel is selected for the operating conditions encountered.

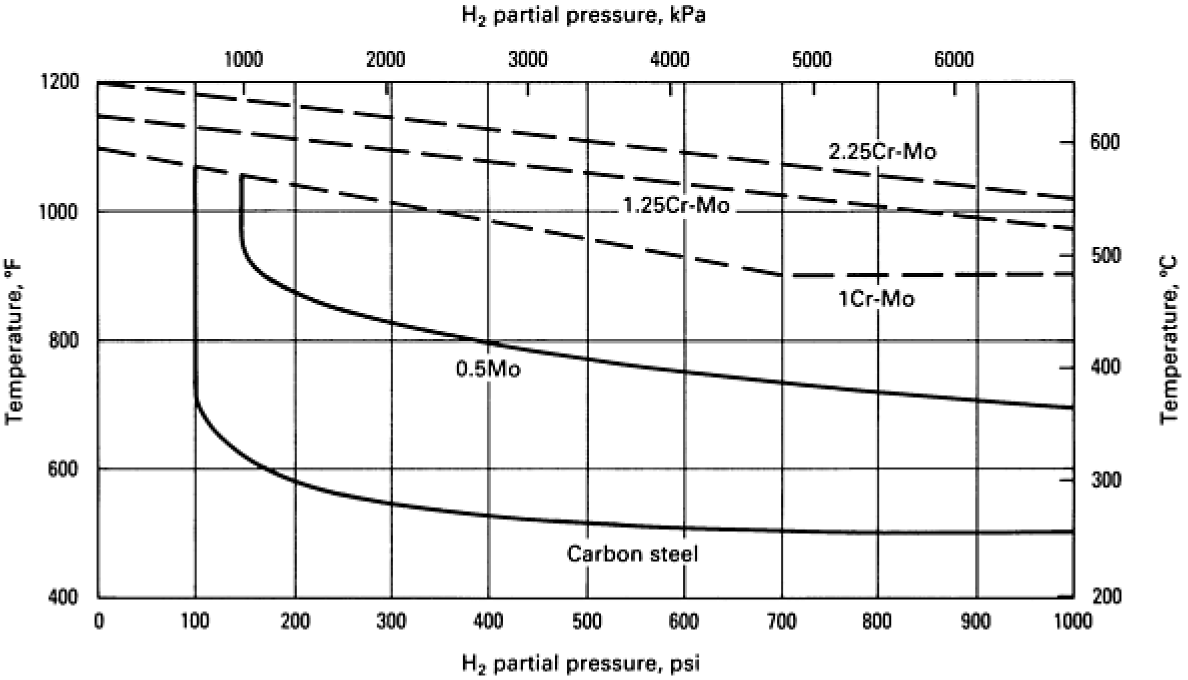

Fig. 27 Operating limits for various steels in high-temperature high-pressure hydrogen service (Nelson curves) to avoid decarburization and fissuring. Source: Ref 146

In addition to hydrogen attack, hydrogen stress cracking can occur at carbon and low-alloy steel welds that were in hydrogen service above approximately 260 °C (500 °F). Cracking is intergranular and typically follows lines of high, localized stress and/or hardness. Cracking is caused by dissolved hydrogen and is prevented by postweld heat treatment. Proper hydrogen outgasing procedures should be followed when equipment is depressurized and cooled prior to shutdown.

Stainless steels with chromium contents above 12% and, in particular, the austenitic stainless steels are immune to hydrogen attack. It should be noted, however, that atomic hydrogen will diffuse through these steels; as a result, they will not provide protection against hydrogen attack if applied as a loose lining or an integral cladding over a nonresistant base steel.

Corrosion Fatigue

Corrosion, in conjunction with cyclic stressing, can bring about a significant reduction in the fatigue life of a metal. Failure under these circumstances is described as corrosion fatigue. Rotating equipment, valves, and some piping runs in refineries and petrochemical plants may be subject to corrosion fatigue. In particular, pump shafts and various springs are the two most likely candidates for corrosion fatigue. The types of springs involved include those of scraper-blade devices in a wax production unit, internal springs in relief valves, and compressor valve springs.

Prevention of Corrosion Fatigue. A number of corrective procedures are available for preventing corrosion fatigue. These include increasing the fatigue resistance and corrosion resistance of the metal involved, reducing the number of stress cycles or the stress per cycle, and removing or inhibiting the corrosive agent in the environment. Fatigue life can often be increased through heat treatments or alloy changes, which make the metal stronger and tougher. Corrosion resistance can be improved by applying protective coatings or by a material change. A design change can eliminate vibration or (in a spring) reduce the stress per cycle. Finally, adding a corrosion inhibitor or removing a source of pitting, such as chlorides, can often increase the corrosion fatigue life of the failing part. Additional information on corrosion fatigue is available in the article “Forms of Mechanically Assisted Degradation” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook.*

Liquid-Metal Embrittlement

Although liquid-metal embrittlement has been recognized for at least 50 years, it has received far less attention than the more commonly encountered hydrogen embrittlement or stress-corrosion cracking. This is due in part to the fact that the probability of liquid-metal contact occurring in refineries and petrochemical plants is normally rather small. In situations in which liquid-metal embrittlement has occurred, it has been mainly due to the zinc embrittlement of austenitic stainless steels. Isolated failures have been attributed to welding in the presence of residues of zinc-rich paint or to the heat treating of welded pipe components that carried splatter of zinc-rich paint. However, most of the reported failures due to zinc embrittlement have involved welding or fire exposure of austenitic stainless steel in contact with galvanized steel components.

For example, in one case, severe and extensive cracking in the weld HAZ of process piping made from austenitic stainless steel occurred in a petrochemical plant during the final stages of construction. Much of the piping had become splattered with zinc-rich paint. Although the welders had been instructed to clean affected piping prior to welding, no cleaning and only limited grinding were performed. After welding, dye penetrant inspection revealed many thin, branched cracks in the HAZ of welds, as shown in Fig. 28.

Fig. 28 Intergranular cracking in HAZ of stringerbead weld on type 304 (S30400) stainless steel pipe due to zinc embrittlement. Weld area had been covered with zinc-rich paint.

In many cases, through-wall cracks cause leaks during hydrotesting. Typically, zinc embrittlement cracks contain zinc-rich precipitates on fracture surfaces and at the very end of the crack tip. Cracking is invariably intergranular in nature (Ref 148).

Several different models for the zinc embrittlement of austenitic stainless steel have been proposed. The most accepted model involves the reduction in atomic bond strength at a surface imperfection or crack tip by chemisorbed zinc metal. Zinc embrittlement is a relatively slow process that is controlled by the rate of zinc diffusion along austenitic grain boundaries. Zinc combines with nickel, and this results in nickel-depleted zones adjacent to the grain boundaries. The resulting transformation of face-centered cubic austenite (γ) to body-centered cubic ferrite (α) in this region is thought to produce not only a suitable diffusion path for zinc but also the necessary stresses for initiating intergranular cracking. Externally applied stresses accelerate cracking by opening prior cracks to liquid metal.

Although the melting point of zinc is 420 °C (788 °F), no zinc embrittlement has been observed at temperatures below 570 °C (1380 °F), probably because of phase transformation and diffusion limitations. There is no evidence that an upper temperature limit exists. In the case of zinc-rich paints, only those having metallic zinc powder as a principal component can cause zinc embrittlement of austenitic stainless steels. Paints containing zinc oxide or zinc chromates are known not to cause embrittlement.

Prevention of Zinc Embrittlement. Obviously, the best approach to the prevention of zinc embrittlement is to avoid or minimize zinc contamination of austenitic stainless steel components in the first place. In practice, this means using no galvanized structural steel, such as railings, ladders, walkways, or corrugated sheet metal, at locations where molten zinc is likely to drop on stainless steel components if a fire occurs. If zinc-rich paints will be used on structural steel components, shop priming is to be preferred. Field application of zinc-rich paints should be done after all welding of stainless steel components has been completed and after insulation has been applied. Otherwise, stainless steel components should be temporarily covered with plastic sheathing to prevent deposition of overspray and splatter.

If stainless steel components have become contaminated despite these precautionary measures, proper cleaning procedures must be implemented. Visible paint overspray should be removed by sandblasting, wire brushing, or grinding. These operations should be followed by acid pickling and water rinsing. Acid pickling will remove any traces of zinc that may have been smeared into the stainless steel surface by mechanical cleaning operations. Suitable acid pickling solutions include 5 to 10% nitric acid, phosphoric acid, or sulfuric acid. Hydrochloric acid should not be used in order to avoid potential pitting or SCC problems. After removal of all traces of acid by water rinsing, final cleaning with naphtha solvent should be performed immediately before welding. Additional information on liquid-metal embrittlement and a related phenomenon—solid-metal embrittlement—can be found in the article “Liquid Metal Induced Embrittlement” and “Solid Metal Induced Embrittlement” in *Corrosion: Fundamentals, Testing, and Protection,* Volume 13A of *ASM Handbook.*

Erosion-Corrosion

Various materials of construction for refinery and petrochemical plant service may exhibit accelerated metal loss under unusual fluid-flow conditions. Attack is caused by a combination of flow velocity (mechanical factors) and corrosion (electrochemical factors) known as erosion-corrosion. Affected metal surfaces will often contain grooves or wavelike marks that indicate a pattern of directional attack. Soft metals, such as copper and aluminum alloys, are often especially prone to erosion-corrosion, as are metals such as stainless steels, which depend on thin oxide films for corrosion protection. Most cases of erosion-corrosion can be mitigated by proper design and/or material changes. For example, by eliminating sharp bends, erosion-corrosion problems can be significantly reduced in process piping. Increasing the pipe diameter of vapor lines will reduce flow velocities and therefore the erosion-corrosion by impinging droplets of liquid. Piping immediately downstream of pressure let-down valves often must be upgraded to prevent accelerated attack due to high flow turbulence.

Cavitation. Cavitation damage is a fairly common form of erosion-corrosion of pump impellers or hydraulic turbine internals. Cavitation is caused by collapsing gas bubbles at high-pressure locations; adjacent metal surfaces are damaged by the resultant hydraulic shock waves. Cavitation damage is usually in the form of loosely spaced pits that produce a roughened surface area. Subsurface metal shows evidence of mechanical deformation. As a general rule, cast alloys are likely to suffer more damage than wrought versions of the same alloy. Ductile materials, such as wrought austenitic stainless steels, have the best resistance to cavitation. Damage can be reduced by design changes, material changes, and the use of corrosion inhibitors. Smooth finishes on pump impellers will reduce damage. Some coatings can be beneficial. Design changes with the objective of reducing pressure gradients in the flowing liquid are most effective.

Mixed-Phase Flow. Accelerated corrosion due to mixed vapor/liquid streams is primarily found in crude and vacuum furnace headers and transfer lines of crude distillation units, in overhead vapor lines and condenser inlets on various fractionation towers, and in reactor effluent coolers of hydrocracking and hydrotreating units.

In general, increases in vapor load and mass velocity increase the severity of high-temperature sulfidic corrosion by crude oils and atmospheric residuum (reduced crude) (Ref 149). Corrosion is least severe with flow regimes in which the metal surface is completely wetted with a substantial liquid hydrocarbon layer. Corrosion is most severe with the spray flow that results from vapor velocities above 60 m/s (200 ft/s) and vapor loads above 60%.

Under these conditions, corrosion rates of certain components, such as furnace headers, furnace-tube return bends, and piping elbows, could increase by as much as two orders of magnitude. This phenomenon is caused by droplet impingement, which destroys the protective sulfide scale normally found on steel components, as shown in Fig. 29. Such impingement damage is usually not seen in straight piping, except immediately downstream of circumferential welds. Damage is usually in the form of sharp-edged laketype corrosion that, because of its appearance, is often confused with naphthenic acid corrosion. As a rule, 5Cr-0.5Mo steel components have sufficient resistance to all but severe cases of droplet impingement in transfer lines. Higher alloys should be used for furnace tubes and associated components, such as headers and return bends.

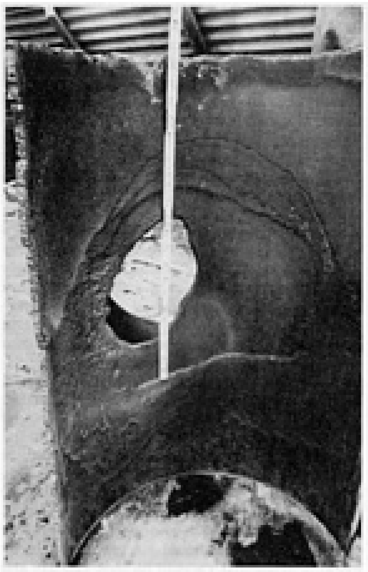

Fig. 29 Accelerated high-temperature sulfidic corrosion in 500-mm (20-in.) diam pipe of vacuum furnace outlet header due to droplet impingement at high vapor velocities

Corrosion damage at elbows of overhead vapor lines is often caused by droplet impingement as a result of excessively high vapor velocities. Typical impingement-type corrosion of tubes and baffles just below the vapor inlet of overhead condensers is shown in Fig. 30. As a general rule, overhead vapor velocities should be kept below 7.5 m/s (25 ft/s) to minimize impingement-type corrosion. In addition, horizontal impingement baffles can be mounted just above the top tube row of overhead condensers.

Fig. 30 Accelerated aqueous chloride corrosion below inlet nozzle of crude tower overhead condenser due to droplet impingement. Note partial loss of carbon steel baffles and localized corrosion along top of admiralty metal (C44300) tubes.

Air-cooled reactor effluent coolers of hydrocracking and hydrotreating units are also prone to impingement-type corrosion. Poor flow distribution through large banks of parallel air coolers can result in excessive flow velocities in some coolers, usually those in the center. The resulting low flow velocities in the outer coolers can cause deposition of ammonium sulfide and/or chloride in these coolers; this blocks the tubes and further increases velocities in the remaining air coolers (Ref 57). This problem is aggravated by low, nighttime air temperatures, which increase deposition problems. Installation of protective sleeves (ferrules) at the inlet tube end has helped to reduce attack in some cases; in others, it has only moved the area of attack to an area immediately downstream of the sleeves. Careful attention to proper flow distribution through redesign of the inlet headers is often the only way of controlling air cooler corrosion.

Entrained Catalyst Particles. Accelerated corrosion due to entrained catalyst particles can occur in the reaction and catalyst regeneration sections of catalytic cracking units. Refractory linings are required to provide protection against oxidation and high-temperature sulfidic corrosion, as well as erosion by catalyst particles, particularly in cyclones, risers, standpipes, and slide valves. Stellite hardfacing is used on some components to protect against erosion. When there are no erosion problems and when protective linings are impractical, austenitic stainless steels such as type 304 (S30400) can be used. Cyclone diplegs, air rings, and other internals in the catalyst regenerator are usually made of type 304 (S30400) stainless steel, as is piping for regenerator flue gas. The main fractionation tower is usually made of carbon steel, with the lower part lined with a ferritic or martensitic stainless steel containing 12% Cr such as type 405 (S40500) or 410 (S41000). Slurry piping between the bottom of the main fractionation tower and the reactor may receive an additional corrosion allowance as protection against excessive erosion.

Corrosion Control

A component in refinery or petrochemical service will require replacement when:

- Corrosion or other deterioration has made it unfit for further service
- It no longer performs satisfactorily, although it may still be operational
- It has become completely nonoperational

Based on the results of a failure analysis, certain corrective measures can be implemented. These include, for example, the use of alternative materials of construction, changes in equipment design and process conditions, the use of corrosion inhibitors, and the application of protective coatings and linings.

Materials Selection. The most common method for preventing repeated failures is selection of improved metals or alloys. If a given piece of equipment fails every other year or so, substitution of a more expensive metal that provides better performance can invariably be justified. In contrast, there is no justification for replacing a carbon-steel tank with one made from a more corrosion-resistant alloy if the tank corroded out after 35 years of service (unless, of course, all of the corrosion occurred during the last 6-month period).

Design Changes. Proper design of equipment is usually as important as proper selection of material. Design changes should involve consideration of changes in strength requirements, changes in material, and the need for additional allowances for corrosion, depending on past experience. Certain rules should be followed to reduce corrosion-related problems:

- Welded joints can be substituted for flanged joints to minimize crevice corrosion
- Equipment can be modified to permit easy cleaning and draining
- Piping for certain equipment, such as pumps, can be modified to allow bypassing or replacement during service
- Mechanical and vibrational stresses can be minimized by providing additional supports to avoid stress-related failures
- Sharp bends in piping can be realigned to prevent erosion-corrosion
- Heat exchangers can be modified to reduce temperature gradients that cause high stresses and also accelerate corrosion problems

Further information on design considerations is available in the articles “Designing to Minimize Corrosion” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Process Changes. Process changes that can be considered for reducing corrosion and other failures include the following:

- Temperature can be decreased to decrease corrosion rates
- Concentrations of critical corrosive species can be adjusted
- Flow velocity can be reduced to prevent erosion-corrosion
- Oxygen (air) can be removed by the use of scavenging chemicals
- Water entry can be controlled by installation of calcium chloride drying equipment, settling drums, or demister screens

Changing the concentration of corrosive contaminants in hydrocarbon streams is usually effective. Certain catalysts, such as hydrofluoric acid, are virtually inert when highly concentrated, but when diluted by water, they become extremely corrosive. Reducing the amount of acid entrained in hydrocarbon streams invariably reduces corrosion problems.

Changes in the flow regime of mixed vapor/liquid streams as a result of velocity changes can have a pronounced effect on corrosion. Very high velocities produce erosion-corrosion problems. Similarly, stagnant conditions must be avoided with metals that form passive oxide films, such as stainless steels.

Deaeration finds widespread application in the treatment of boiler feedwater. The corrosion of certain nickel alloys by hydrofluoric acid can be controlled by excluding air. However, metals that depend on passive oxide films for corrosion resistance may actively corrode in certain environments if air is excluded.

Corrosion Inhibitors. Filming-amine corrosion inhibitors are added in small concentrations to various process streams to help control corrosion. Filming-amine inhibitors become ineffective at temperatures above approximately 175 °C (350 °F)--not because they decompose, but because the rate of desorption begins to exceed the rate of adsorption. The inhibitors are primarily used to protect overhead condensing equipment. So-called water-dispersible types contain surfactants to allow addition to streams that contain excess water. In general, filming-amine inhibitors are continuously injected at a rate that is just sufficient to maintain protection. Higher-than-normal dosages are required for several days to establish a protective film after inhibitor injection has been interrupted (for example, because of pump failure) or after a shutdown. Most filming-amine inhibitors will tend to solubilize prior corrosion products; this can lead to fouling

problems in downstream equipment. In amine units, these inhibitors usually cause foaming problems. Detailed information is available in the articles "Corrosion Inhibitors for Oil and Gas Production" and "Corrosion Inhibitors for Crude Oil Refineries" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Protective Coatings. Although most refineries and petrochemical plants do not rely on organic coatings for corrosion control, because a fire would immediately destroy these, extensive use is made of metallic cladding and refractory linings. Cladding is usually performed at the mill by rolling a relatively thin sheet of a corrosion-resistant metal or alloy to a thicker base metal at elevated temperatures. The finished product will exhibit a fully bonded, metallurgical joint. Clad plates can be formed and fabricated into vessels or piping by welding the joints of the base metal and overlaying the welds. Thin sheet strips of corrosion-resistant alloy can be attached by spot welding in the field to protect an unclad vessel. This process is known as strip lining. For long-term service, however, cladding tends to be more reliable than strip lining. Strip lining can become a source of problems with process streams that contain hydrogen at elevated temperatures and pressures or that evolve hydrogen because of corrosion. In either case, pockets of hydrogen can build up behind the lining and cause it to fail. Cladding by explosive bonding is primarily used for new construction to attach titanium or nickel-alloy-overlays.

Overlays of corrosion-resistant alloys can also be attached in the form of adjacent weld beads. For example, reactor vessels for hydrocracking and hydrotreating units are protected against high-temperature sulfidic corrosion with a weld overlay of type 347 (S34700) stainless steel.

Spray metallized coatings, as a rule, have not been extensively used in refinery and petrochemical plant applications, because such coatings have not been very reliable. In contrast, diffusion coatings, particularly aluminized coatings, have been highly successful as an alternative approach to controlling high-temperature sulfidic corrosion of carbon steel and low-alloy steel components. Aluminizing not only provides resistance to high-temperature sulfidic corrosion but also reduces scaling, carburization, coking, and erosion problems (Ref 150). Aluminized components are not necessarily less costly than those made of higher-alloy steels or stainless steels and a detailed cost analysis is usually required. Aluminizing is a proprietary process in which steel components are packed into a retort and exposed to aluminum vapor at a temperature above about 925 °C (1700 °F). The aluminum diffuses into the steel, and this forms a true metallurgical alloy containing over 50% Al at the surface.

Other methods for forming a corrosion-resistant iron-aluminum layer on steel surfaces include flame spraying and hot dipping, either with or without subsequent diffusion heat treatments. As a rule, these methods have been less effective than aluminizing, primarily because of nonuniform thickness, porosity, and holidays (Ref 151).

The aluminizing of carbon steel or low-alloy steel components typically increases their resistance to high-temperature sulfidation by two orders of magnitude (Ref 152). However, the diffused iron-aluminum layer is only 0.08 to 0.4 mm (3 to 15 mils) thick, depending on the base alloy, and can be readily damaged by mechanical (tube drilling for coke removal) or chemical means (acid or caustic cleaning). Aluminized components also require special fabrication techniques, including welding and roller expanding. Distortion and shrinkage during aluminizing can be a problem with some components.

A variety of processes for applying protective coatings are discussed in the Section "Corrosion Protection Methods" in this Volume. Methods for applying weld claddings are discussed in the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in *Welding, Brazing, and Soldering,* Volume 6 of *ASM Handbook.*

Refractory Linings. Refractory materials are used in refineries and petrochemical plants as linings to protect steel from thermal degradation, erosion damage, and both low- and high-temperature corrosion. Unlike thin organic linings and coatings, refractory linings are applied in thicknesses of 25 to 100 mm (1 to 4 in.) or more. Metal wire reinforcement is used to help hold the lining in place.

Portland cement/sand is the lining that is most commonly used to protect steel against mild corrosives. This lining (frequently called gunite or shotcrete, after the application technique) has been used in refineries for more than 50 years. The primary application is sour water service with a pH value between 4 and 8. The material is low cost, and the application is straightforward. The mixture is applied with a pneumatic gun that shoots the premixed cement, sand, and water onto the vessel surface. A chicken-wire metal reinforcement is usually provided at the mid-thickness of the 25- to 40-mm (1- to 1.5-in.) thick lining. As with any other concrete, the lining must be cured before it is placed into service. During ambient-temperature curing, shrinkage cracks may occur, but they are not detrimental to the serviceability of the lining. Acidic water entering the cracks is neutralized by the alkalinity of the concrete and is trapped in the crack.

However, continuing acid attack will result in gradual loss of thickness (much like corrosion), and aggregate, which is carried away in the process fluid, may cause erosion or plugging in downstream equipment, such as filters, pumps, and valves.

For highly acidic solutions or for higher temperatures, more resistant cements and aggregate are used, such as Lummite-Haydite cement Special acid-resistant cements based on silicate, furane, phenolic, and sulfur compounds are used for highly acidic services, but at the cost of reduced resistance to alkaline solutions. In addition to gunning, these cements can be applied as thinner coatings by troweling.

For hot, highly acidic solutions, acid-proof brick linings can be used. The essential components of such a lining are a membrane lining against the steel shell, topped with brick-and-mortar construction. A membrane is placed between the bricks and the steel shell because brick-and-mortar construction is inherently porous and subject to capillary leakage. Membrane materials need not be completely immune to attack by the corrosive, because any swelling of the membrane will tend to seal off the bottoms of the capillary channels. Furthermore, the brick lining does provide thermal insulation, which reduces the temperature and therefore the aggressiveness of the corrosive. Typically, one course of 115-mm ($4\frac{1}{2}$-in.) thick brick raises the temperature limit of a membrane material by about 30 °C (55 °F), and two courses by about 50 °C (90 °F).

The membranes range from thermoplastic resins and elastomers to sheet or bonded lead linings, depending on the corrosive handled and the need to accommodate relative movement between the shell and the brick lining. Ceramic brick is satisfactory for all common operating conditions and corrosives, except strong alkalies, hydrofluoric acid, and fluorides, which require carbon brick. As a rule, acid-proof brick linings have limited applications in refineries and petrochemical plants, the principal uses being storage tanks for sulfuric acid. They are seldom used for pressure vessels, especially those that operate at elevated temperatures and pressures.

Heat-resistant linings can reduce the cost of pressure vessels that will operate at temperatures above 345 °C (650 °F). Allowable stresses, given in the ANSI/ASME Boiler and Pressure Vessel Code, Section VIII, for the design of carbon steel vessels, decrease with increasing temperatures. Because the maximum permissible temperature is 510 °C (950 °F), alloy steels must be used above this temperature. A heat-resistant lining, by reducing the metal temperature, will reduce the required wall thickness of carbon steel vessels, such as reactors. Alternatively, heat-resistant linings allow the use of carbon steel vessels at higher temperatures, such as reactors in fluid catalytic cracking units. For either of these applications, the integrity of the lining is important because loss of insulation can result in areas of the vessel reaching temperatures above the acceptable mechanical design limit (hot spots). When hot spots are found, temperatures can be reduced by air blowing or steam sprays. If this is not effective, the unit must be immediately taken out of service for repair of the lining. Properly applied linings will be effective for extended time periods and require repairs only during normally scheduled shutdowns.

The heat-resistant and insulating linings used in pressure vessels are refractory materials that are applied as monolithic linings by pneumatic gunning, casting, or hand packing. The most common types are the hydraulic-setting castable refractories. Their ease of application, generally good performance, and variety of strength and insulating characteristics make them versatile high-temperature materials. The quality of the applied castable material depends on the product quality as produced by the manufacturer, the experience of the applicator, and the manner in which heat is first applied to the material after it is installed. Erosion-resistant linings are relatively thin (40 mm, or $1\frac{1}{2}$ in.) layers of dense refractories that are supported by V-anchors or hexmesh welded directly to the vessel shell. To improve the serviceability of V-anchored linings, metal fibers are often added to the refractory mix before placement.

Catalytic cracking units, with their associated cyclones, transfer lines, and slide valves, represent the single largest application of refractories in refineries (Ref 153). The regenerator vessels, and sometimes the reactors, are lined with 100 to 150 mm (4 to 6 in.) of refractory concrete, which must withstand oxidizing (regenerator) or reducing (reactor) conditions at 540 to 760 °C (1000 to 1400 °F). The moving catalyst bed produces mild erosion, and mechanical or thermal spalling is frequently encountered. Cyclones and catalyst transfer lines are usually subjected to extreme erosion from fluidized catalyst at temperatures between 315 and 760 °C (600 and 1400 °F). Transfer lines are subjected to heavy loadings of catalyst at velocities of 7.5 to 15 m/s (25 to 50 ft/s). Slide valves in transfer lines and standpipes are subject to severe erosion, but must maintain their original thickness so they can control catalyst flow. Care must be exercised in designing the slide valve because of thermal expansion differentials. Plug valves have more tolerance for thermal expansion differentials and are frequently lined with refractory.

Because operating conditions in reformer reactors include hydrogen-rich vapors at temperatures near 500 °C (950 °F), special care is required in designing refractory liners because of the increased thermal conductivity of hydrogen-saturated refractories. Reformers in hydrogen and ammonia plants operate at temperatures of 1100 to 1370 °C (2000 to 2500 °F) and therefore require refractories of very low silica content. Furnaces are typically lined with refractory castables or insulating fire brick. Thermal shock and temperature cycling are the primary agents of attack. Mechanical movement, nut blasting, and similar forces also contribute to deterioration. Floors are usually made of dense refractory concrete or fire brick in order to resist foot traffic and mechanical impact during turnarounds. Stacks and breechings for most types of refinery units have similar service requirements: strength at high temperatures and resistance to corrosion, erosion, and spalling. Temperatures range from 205 to 815 °C (400 to 1500 °F), and the flue gas may contain catalyst, sulfur oxides, hydrogen sulfide, or carbon monoxide. Water or steam may be injected into the gas stream to control temperature.

If conditions are mild, with temperatures below 540 °C (1000 °F) and little or no erosion, insulating or semi-insulating refractory concrete on independent anchors makes a serviceable lining. More erosive conditions may require the use of dense high-strength refractory castable.

High-sulfur fuels generate sulfuric acid in the cooler zones of stacks and breechings where temperatures drop below the acid dew point, ranging from 150 to 177 °C (300 to 350 °F). Acid attacks many conventional refractory castables containing calcium aluminate cement. The alkali-silicate and some calcium aluminate base materials are moderately acid resistant and will withstand condensing flue gas vapors. For many furnace stack linings, densely applied semi-insulating refractory concrete is satisfactory.

Incinerators operate at temperatures as high as 1540 °C (2800 °F) and are particularly susceptible to slag and fly-ash attack because they often burn waste products. Problems can be expected with fluids containing alkalies and transition metals. Thermal shock can be a problem if water is injected to control temperatures or if the burner unit is allowed to cycle on and off several times a day, with periods of cooling in between. Phosphate-bonded alumina type castables are probably the best materials for this type of service. Additional information on refractory linings can be found in the article "Chemical-Setting Ceramic Linings" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Corrosion of Pipelines

C.G. Siegfried, Ebasco Services Inc.

Introduction

PIPELINES play an extremely important role throughout the world as a means of transporting gases and liquids over long distances from their sources to the ultimate consumers. The general public is not aware of the number of pipelines that are continually in service as a primary means of transportation. A buried operating pipeline is rather unobtrusive and rarely makes its presence known except at valves, pumping or compressor stations, or terminals. Because pipelines are hidden from view, they are not as noticeable as drilling rigs, refineries, or gas-processing plants.

At present, there are approximately 460,000 km (285,000 miles) of common carrier pipelines transporting about 46% of all the crude oil and refined products moved in the United States. In 1984, there were more than 1.6×10^6 km (10^6 miles) of natural gas pipelines in service in the United States; about 25% of this was in interstate service. At that time, there were approximately 280,000 km (174,000 miles) of pipelines carrying liquids an interstate service in the United States. Construction continues to add more miles of pipelines. In 1986, 9800 km (6090 miles) of natural gas pipeline were constructed, along with 5740 km (3567 miles) of crude oil pipelines and 2660 km (1652 miles) of pipeline for refined products. With this vast network of constantly functional pipelines in use moving natural resources and end products to locations where they are utilized, it becomes apparent that keeping them in service through the prevention of corrosion is technologically and economically advantageous.

Corrosion control of pipelines throughout the world is accomplished in the vast majority of cases through the use of cathodic protection combined with a suitable dielectric coating. The cathodic protection system applies protective current to the outer surface of the pipeline steel where it is exposed to the adjacent soils at imperfections in the coating system. The coating system serves to reduce greatly the total amount of protective current required during the operating life of the pipeline. Corrosion control considerations should begin in the design phase of a pipeline and should be continued through the construction phase and the entire economic life of the pipeline.

This article will address only transmission and distribution pipelines and pipe-type electrical system cables; information on the corrosion of underwater pipelines is available in the article “Marine Corrosion” in this Volume. Corrosion of buried telephone cables is discussed in the article “Corrosion in Telephone Cable Plants” in this Volume. The analysis of pipeline failures is addressed in the article “Failures of Pipelines” in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook*.

Causes of Pipeline Corrosion

Dissimilar Soils. A buried pipeline, even one of a relatively short length, will almost inevitably encounter soils that have varying compositions. There can be variations of a physical nature (for example, differences in coarseness and grain size) as well as variations in type (for example, rock, loam, and clays). Additional variations can be of a chemical nature, such as pH and chemical constituents.

When a pipeline traverses dissimilar soils, the pipeline steel in a particular soil electrolyte will often assume a galvanic potential that is somewhat different from the potential of portions of the same pipeline traversing dissimilar soils elsewhere along the pipeline route. Such galvanic potential differences between different areas of a single pipeline can occur on a macroscale (that is, over many miles in the route of the pipeline) or on a microscale (within inches of each other or even over shorter distances).

Differential Aeration. A pipeline traversing soils that have varying levels of oxygen concentration will be subject to corrosion cell activity where the portion of the pipeline steel in the area of lowest oxygen concentration is anodic to other areas of the pipeline where there is a greater concentration of oxygen. This form of corrosion activity is also referred to as a concentration cell.

Dissimilar Metals. Pipelines having dissimilar materials of construction (for example, carbon steel pipe with brass cocks or valves) that are in contact with a common electrolyte with no electrical isolation between the two metals can be subject to intense corrosion (see the article "Galvanic Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*). The metal that is highest in the galvanic series (Table 1) will be anodic to metals lower in the series. An example of dissimilar-metal corrosion is the use of magnesium alloys, aluminum alloys (in seawater), and zinc as galvanic (sacrificial) anodes for the protection of carbon steel structures such as pipelines.

Table 1 Practical galvanic series of metals and alloys in neutral soils and water

Metal or alloy	Potential, V[a]
Most active	
Commercially pure magnesium	-1.75
Magnesium alloy (Mg-6Al-3Zn-0.15Mn)	-1.16
Zinc	-1.1
Aluminum alloy (5% Zn)	-1.05
Commercially pure aluminum	-0.8
Low-carbon steel (clean and shiny)	-0.5 to -0.8
Low-carbon steel (rusted)	-0.2 to -0.5
Cast iron (no graphitized)	-0.5
Lead	-0.5
Low-carbon steel in concrete	-0.2
Copper, brass, bronze	-0.2
High-silicon cast iron	-0.2
Mill scale on steel	-0.2
Carbon, graphite, coke	+0.3
Most noble

(a) Typical potential normally observed in neutral soils and water, measured with respect to copper sulfate reference electrode.

New and Old Steel Pipe. As indicated in Table 1, the potential of steel located in a neutral electrolyte as measured against a copper-copper sulfate reference electrode can vary within a range of -0.2 to -0.8 V. The potential of a particular piece or section of steel is largely determined by the condition of the steel surface that contacts the electrolyte. Bright, new steel or old steel that has been mechanically restored to a shiny pristine surface condition will exhibit a potential between -0.5 and -0.8 V. Old, rusty steel will have a potential from -0.2 to -0.5 V. With bright, new steel pipe that is electrically connected to older or superficially rusted steel pipe in an electrolyte, galvanic potential differences as great as 0.5 V can exist in which the new pipe is anodic to the older, rusty pipe.

Bacteriological Corrosion. Microorganisms existing in a pipeline trench can affect the control of corrosion either directly or indirectly. Anaerobic bacteria, which thrive in the absence of oxygen, are sulfate-reducing organisms that consume hydrogen and cause a loss of polarization at the steel pipe surface. This loss of polarization can make the attainment of successful cathodic protection much more difficult.

Other bacteria that oxidize sulfur can exist in aerated environments. These bacteria (*Thiobacillus Thioxidans*) consume oxygen and oxidize sulfides into sulfates, such as sulfuric acid (H_2SO_4). By their metabolic processes, these bacteria can create concentrations of H_2SO_4 as high as 10%. Such an environment can be particularly hazardous to pipeline steel. Microbiological corrosion activity is discussed at length in the article "Microbiologically Influenced Corrosion" in *Corrosion: Fundamentals, Testing, and Protection,* Volume 13A of *ASM Handbook.*

Interference-current effects are also referred to as stray-current effects. They usually occur when the direct currents associated with a foreign metallic system (one not directly associated with the pipeline of concern) use the pipeline steel as a preferential conductor in returning to their source. When this occurs, the currents will couple to the pipeline steel from the soil and flow longitudinally on the steel to a location or locations where they discharge from the steel to the adjacent soils in order to complete their circuit.

The hazard to the affected pipeline is primarly to the steel in the locations where current discharges to the earth; in so doing, it is in essence creating anodic areas with the attendant loss of pipe metal. Current pickup locations can also be

hazardous to the corrosion control system of the affected pipeline if the current density being collected is of sufficient magnitude to incur hydrogen overvoltage conditions. The formation of gaseous hydrogen at dielectric coating imperfections can cause coating damage and can create hydrogen cracking effects on certain higher-strength steels. There are generally two types of interference-current activity: steady state and transient.

Steady State. In this type of interference-current activity, the magnitude of the interference current is essentially a constant. Such currents are usually incurred by the operation of other nearby impressed-current cathodic protection systems. Because all of the systems involved (the affected pipeline and the other cathodic protection system) are fixed with regard to location, the stray-current flow patterns are constant, and analysis through field testing is relatively straightforward.

Transient. In this type, the source of the stray current is the operation of a fraction system (electrified railroad, subway, mining equipment) that uses direct current (dc) series motors for propulsion and the rail system as the return leg to their dc power source (for example, a substation). Such traction equipment will often have the positive feed to the vehicle motor through an overhead catenary wire or third rail. The negative return leg consisting of the surface-mounted rails can allow the return currents to couple at least partially to buried metallic shunt conductors, such as pipelines and buried metallic sheath cables.

A rail system with poorly bonded rails can represent a high-resistance intended current path. This current path can multiply the resultant stray-current magnitude picked up on adjacent pipelines, cables, and other subsurface metallic structures.

Again, the major hazard caused by a dc traction system to a buried pipeline is the are or areas where the stray current discharges from the pipeline to the adjacent soil to return to its source. In addition, the magnitude of these stray traction currents can be hundreds or even thousands of amperes.

Assessment of these stray traction currents can be very difficult because their magnitude varies as a function of the accelerating and loading demands on all the individual dc motors in the system. Because the stray-current sources are usually moving vehicles, their locations, and therefore the locations at which the stray-current couples initially to earth, can be a constantly shifting pattern. More information on this phenomenon is available in the article “Stray-Current Corrosion” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Corrosion Control and Prevention

Materials Selection. The selection of materials for pipeline construction is limited when all of the aspects of safety, structural integrity, operating life, and economic considerations are taken into account and acted upon.

Carbon steel is the almost exclusive choice of pipeline designers. This is true for pipeline systems that are used to gather or collect the natural gas, crude oil, or water; it is also true for those pipelines that are used to transport substances over distances of hundreds of feet to hundreds of miles. It is also the case for piping systems that are used to distribute natural gas, water, water-refined liquids, and so on, to the end user.

Cast iron is extensively used in water and natural gas distribution systems. In recent years, nonmetallic materials have found application in natural gas distribution systems as carrier vehicles and as liners for restoring failed metallic piping to service without the need for trenching and replacement.

Carbon steels and, in certain types of service or environmental conditions, alloy steels are by far the most commonly used pipeline materials of construction. Table 2 lists compositions of some standard pipe steels.

Table 2 Typical compositions of ASTM and API pipe steels

(a) Niobium, vanadium, and titanium are used at manufacturer's option.

Protective (Dielectric) Coatings. The function and desired characterized of a dielectric-type pipeline coating are covered in NACE RP-01-69. This specification states that the function of such coatings is to control corrosion by isolating the external surface of the underground or submerged piping from the environment, to reduce cathodic protection requirements, and to improve (protective) current distribution. Coatings must be properly selected and applied, and the coated piping must be carefully installed to fulfill these functions. Different types of coatings can accomplish the desired functions. The desired characteristics of the coatings are:

- Effective electrical insulation. For preventing the electrolytic discharge of current from the steel surface of the pipe, the coating must have the characteristics of an effective dielectric material
- Effective moisture barrier. The permeation of a coating material by soil moisture would significantly reduce its dielectric properties
- Application considerations. The coating must be capable of being readily applied to the pipe, and it must not of itself or through required application procedures adversely affect the properties of the pipe. In addition, the coating system must be capable of application to the pipe with a minimum of defects
- Good adhesion to the pipe surface is required to prevent soil moisture migration between the pipe steel surface and the coating inner surface
- Ability to resist holidays with time. With a pipeline in place and backfilled, soil stress and soil contaminants--two primary considerations--can cause coating degradation. Soil stress, which can be brought about by seasonal variations in soil moisture content, can create significant forces on the

coating that can wrinkle, tear, or thin areas of the coating. Contaminants in the soils adjacent to the coating can also seriously affect its long-term performance. Such contaminants can be chemical, such as solvents from leaks in a product pipeline. Microorganisms in the soil can also have a marked effect, as described in the section "Bacteriological Corrosion" in this article
- Ability to resist damage during handling, storage, and installation
- Ability to maintain substantially constant electrical resistivity over time. Because the corrosion control systems of most pipelines consist of the combination of coating and cathodic protection, it is desirable that the dielectric properties of the coating deteriorate at the minimum rate possible. Significant deterioration of the coating with time would otherwise result in a constant requirement for additional catholic protection current, which would be both a technical and economic burden on the pipeline operator.
- Resistance to disbonding. With the cathodic protection current applied and collecting on those portions of the pipelines steel exposed to the soil at coating holidays, there is the possibility of generation of gaseous hydrogen at the steel surface. The gaseous hydrogen can lift the coating edge adjacent to the holiday, thus worsening a bad situation. Therefore, resistance to electrically induced disbondment is an important coating property
- Resistance to chemical degradation
- Ease of repair
- Retention of physical characteristics

Types of Coatings. The pipe coating systems currently in use include the following generic types. Detailed information on paint and coating formulation and application for corrosion protection is available in the article "Organic Coatings and Linings" in *Corrosion: Fundamentals, Testing, and Protection,* Volume 13A of *ASM Handbook.*

Bituminous enamels are formulated from coal tar pitches or petroleum asphalts and have been widely used as protective coatings for more than 65 years. Coal tar and asphalt enamels are available in summer or winter grades. These enamels are the corrosion coating; they are combined with various combinations of fiberglass and/or felt to obtain mechanical strength for handling. The enamel coatings have been the workhorse coatings of the industry, and when properly selected and applied, they can provide efficient long-term corrosion protection.

Enamel systems can be designed for installation and use within an operating temperature range of 1 to 82 °C (30 to 180 °F). When temperatures fall below 4.4 °C (40 °F), added precautions should be taken to prevent cracking and disbonding of the coating during field installation. Enamels are affected by ultraviolet rays and should be protected by kraft paper or whitewash. Enamels are also affected by hydrocarbons, and the use of a barrier coat is recommended when known contamination exists. Bituminous enamel coatings are available for all sizes of pipe. In recent years, the use of enamels has declined for the following reasons:

- Reduced number of suppliers
- Restrictive environmental and health standards from the Occupational Safety and Health Administration, the Environmental Protection Agency, and the Food and Drug Administration
- Increased acceptance of plastic coating materials
- Alternative use of coating raw materials as fuels

Asphalt mastic pipe coating is a dense mixture of sand, crushed limestone, and fiber bound together with a select air-blown asphalt. These materials are proportioned to secure a maximum density of approximately 2.1 g/cm^3 (132 lb/ft^3. This mastic material is available with various types of asphalt. Selection is based on operating temperature and climatic conditions to obtain maximum flexibility and operating characteristics. This coating is a thick (12.7 to 16 mm, or to in.) extruded mastic that results in a seamless corrosion coating.

Extruded asphalt mastic pipe coating has been in use for more than 50 years. It is the thickest of the corrosion coatings and is cost effective for offshore installations.

Asphalt mastic systems can be designed for installation and use within an operating temperature range of 4.4 to 88 °C (40 to 190 °F). Precautionary measures should be taken when handling asphalt mastics in freezing temperatures. Whitewash is used to protect it from ultraviolet rays, and this should be maintained when in storage. This system is not intended for use above ground or in hydrocarbon-contaminated soils. This coating is available on 11.4- to 122-cm (4 -to 48-in.) outside diameter pipe.

Liquid Epoxies and Phenolics. Many different liquid systems are available that cure by heat and/or chemical reaction. Some are solvent types, and others are 100% solids. These systems are primarily used on larger-diameter pipe when conventional systems may not be available or when they may offer better resistance to operation temperatures in the 95-°C (200-°F) range.

Generally, epoxies have an amine or a polyamide curing agent and require a near-white blast-cleaned surface (NACE No. 2 or SSPC SP10). Coal tar epoxies have coal tar pitch added to the epoxy resin. A coal tar epoxy cured with a low molecular weight amine is especially resistant to an alkaline environment, such as that which occurs on a cathodically protected structure. Some coal tar epoxies become brittle when exposed to sunlight.

Extruded plastic coatings fall into two categories based on the method of extrusion, with additional variations resulting from the selection of adhesive. The two methods of extrusion are the crosshead or circular die and the side extrusion or T-shaped die. The four types of adhesives are asphalt-rubber blend, polyethylene copolymer, butyl rubber adhesive, and polyolefin rubber blend.

To date, of the polyolefins available, polyethylene has found the widest use, with polypropylene being used on a limited basis for its higher operating temperature. It is a recognized fact that the perfect pipe coating system does not exist. Each type or variation of adhesive and method of extrusion offers different characteristics based on the degree of importance to user of certain measurable properties.

Fusion-bonded epoxy coatings are heat-activated, chemically cured coating systems. The epoxy coating is furnished in powdered form and, with the exception of the welded field joints, is plant applied to preheated pipe, special sections, connections, and fittings using fluid bed, air spray, or electrostatic spray methods.

Fusion-bonded epoxy coatings were introduced in 1959 and were first used as an exterior pipe coating in 1961. These coatings are applied to preheated pipe surfaces at 218 to 244 °C (425 to 475 °F). Some systems may require a primer system, and some require postheating for complete cure. A NACE No. 2 (SSPC SP10) near-white blast-cleaned surface is require. The coating is applied to a minimum thickness of 0.3 mm (12 mils); in some applications, coating thicknesses range to 0.64 mm (25 mils), with the restriction not to bend pipe coated with a film thickness greater than 0.4 mm (16 mils). The epoxy coatings exhibit good mechanical and physical properties and are the most resistant to hydrocarbons, acids, and alkalies.

A primary advantage of the fusion-bonded pipe coatings is that they cannot hide apparent steel defects; therefore, the steel surface can be inspected after it is coated. The number of holidays that occur is a function of the surface condition and the thickness of the coating specified. Increasing the thickness minimizes this problem, and the excellent resistance to the electrically induced disbondment of these coatings has resulted in their frequent use as pipeline coatings.

Mill-applied tape systems have been in use for more than 30 years on pipelines. For normal construction conditions, prefabricated cold-applied tapes are applied as a three-layer system consisting of a primer, corrosion-preventive tape (inner layer), and a mechanically protective tape (outer layer). Tape systems are available on 5- to 305-cm (2- to 120-in.) outside diameter pipe.

The function of the primer is to provide a bonding medium between the pipe surface and the adhesive or sealant on the inner layer. The inner layer tape consists of a plastic backing and an adhesive. This layer is the corrosion-protective coating; therefore, it must provide a high electrical resistivity, low moisture absorption and permeability, and an effective bond to the primed steel surface. The minimum thickness is usually 3.7 mm (145 mils), with the total system being a minimum of 10 mm (400 mils) thick. The outer layer tape consists of a plastic film and an adhesive composed of the same types of materials used in the inner tape or materials that are compatible with the inner layer tape. The purpose of the outer layer tape is to provide mechanical protection to the inner layer tape and to be resistant to the elements during outdoor storage. The outer layer tape is usually a minimum of 0.64 mm (25 mils) in thickness.

The cold-applied multilayer tape systems are designed for plant coating operations and result in a uniform, reproducible, holiday-free coating over the entire length of any size pipe. The multiple-layer system allows the coating thickness to be custom designed to meet specific environmental conditions. These systems have been engineered to withstand normal handling, outdoor weathering, storage, and shipping conditions.

Waxes. Wax coatings have been in use for more than 48 years and are still employed on a limited basis. Microcrystalline wax coatings are usually used with a protective overwrap. The wax serves to waterproof the pipe, and the wrapper protects the wax coating from contact with the soil and affords some mechanical protection. The most prevalent use of wax coating is the over-the-ditch application with a combination machine that cleans, coats, wraps, and lowers into the ditch in one operation. The lack of objectionable or toxic fumes or smoke should make this system more acceptable.

Polyurethane Thermal Insulation. Efficient pipeline insulation has grown increasingly important as a means of operating hot and cold service pipelines. This is a system for controlling heat transfer in above- or belowground and marine pipelines. Polyurethane insulation is generally used in conjunction with a corrosion coating, but if the proper moisture vapor barrier is used over the polyurethane foam, effective corrosion protection is attained.

Concrete. Mortar linings and coatings have the longest history of use in protecting steel or wrought iron from corrosion. When steel is encased in concrete, a protective iron oxide film forms. As long as the alkalinity is maintained and the concrete is impermeable to chlorides and oxygen, corrosion protection is obtained.

The use of concrete as a corrosion coating is currently limited to internal lining. External application is usually employed over a corrosion-resistant coating for armor protection and negative buoyancy in marine environments.

Metallic (Galvanic) Coatings. Pipe coated with a galvanic coating, such a zinc (galvanizing) or cadmium, should not be utilized in direct burial service. Such metallic coatings are intended for the mitigation of atmospheric-type corrosion activity on the substrate steel.

Cathodic Protection. Some of the mechanisms or circumstances that can create anodic and cathodic areas on a steel pipeline or can make areas on the steel pipeline anodic to adjacent buried metallic structures were discussed in the section "Causes of Pipeline Corrosion" in this article. At the anodic areas on a pipeline, the electrochemical phenomenon known as corrosion causes metallic ions to be lost to the electrolyte in an irreversible manner. At the anodic areas, the conventional current discharges from the pipeline steel flow through the electrolyte to cathodic areas of structures.

The magnitude of the corrosion cell current is proportional to the driving potential between the anodic and cathodic areas and is inversely proportional to the resistance of the total path along which it flows. The total path resistance consists of the anode/electrolyte (soil) interface, the electrolyte itself, the electrolyte/cathodic interface, and the longitudinal resistance of the metallic paths traversed.

Two principal methods are used to eliminate, or at least significantly reduce, the corrosion current flow. The first approach involves increasing the resistance of the circuit over which the corrosion cell potential is impressed. Dielectric coatings attempt to accomplish this, but because holidays in a coating are inevitable in the case of a soil-buried pipeline, and corrosion circuit or circuits retain a finite resistance path.

The second approach consists of eliminating the open-circuit potential differences between anodic and cathodic areas. When there is no driving potential across the corrosion cell circuits, no corroding current can flow. Cathodic protection can be used to accomplish this method of control. Cathodic protection is obtained by causing a direct current to flow form a source external to the pipeline, through the electrolyte, and to the pipeline steel surface in contact with the electrolyte.

If all of the steel surface is collecting current from the adjacent electrolyte, no current can be discharging from the previously anodic areas of the pipeline; therefore, corrosion activity ceases on the pipeline steel. In essence, if the application of the protective current causes all exposed steel surfaces to become cathodes, cathodic protection has been properly established.

To establish a cathodic protection system for a pipeline, the protective current is discharged into the electrolyte from its source. This source consists of objects, usually metallic, that are properly located in the electrolyte and commonly referred to as anodes or a ground bed. These devices are correctly referred to as anodes because, in discharging the protective current to the electrolyte, they are consumed through the irreversible loss of metallic ions.

There are two primary methods of establishing a cathodic protection system for a pipeline. One is to use anodes made of metals or alloys that, by virtue of their place in the galvanic series of metals, will be anodic to the steel when connected to the pipeline electrically and located in the same electrolyte. Such anodes are known as galvanic anodes or sacrificial anodes. Common anode metals for land or marine pipelines are high-purity zinc and certain magnesium alloys. For marine pipelines, a number of aluminum alloys are also used.

In the second method of establishing cathodic protection for pipelines, the current for the anode system is provided by an external source. The most common source used for the protective current is a transformer-rectifier system in an appropriate housing. The input of the source is commercial alternating current (ac) that is transformed down to the required level and then rectified to a dc voltage of that level. The dc voltage output, when applied between the pipeline steel and the anode system through insulated conductors, creates a protective current flow. Such powered cathodic protection systems are commonly referred to as impressed-current systems.

The materials used for the anodes in impressed-current systems are usually selected for their low consumption rates, that is, relatively low amounts of metal consumed per ampere of current discharged per year. Such materials include graphite, high-silicon cast iron, a thin layer of platinum overlaying a titanium or niobium substrate, certain ferrites, certain conductive polymers, and carbon steel pipe or rails. Steel does not have a low consumption rate, but is usually used when availability of the pipe or rails has economic benefit.

Alternative power sources for impressed-current systems include engine-driven generators, photovoltaic arrays, fuel cells, thermoelectric generators, and wind-powered generators. As a general rule, galvanic anodes are used where relatively low amounts of protective current are required from an individual protective system. Impressed-current installations can provide hundreds of amperes each, but for pipeline applications, typical dc output ratings for individual installations would range from 10 to 60 A at 10 to 70 V. More information on equipment and applications for cathodic protection is available in the article “Cathodic Protection” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Design Considerations. Proper corrosion control of a pipeline is most effectively and economically begun during the design stage of the pipeline. Factors affecting the efficacy of the corrosion control program for the pipeline are discussed below.

The terrain, soils, and waters in which the pipeline will be located should be considered in order to determined the most effective and most durable coating system for the pipeline. These factors also have a direct bearing on the type and amount of cathodic protection that will be required for corrosion control. Harsher and more aggressively corrosive soils can require protective current densities to be raised, thus increasing total current requirements for a given pipeline system.

Adjacent or crossing pipeline systems to the proposed pipeline right-of-way must also be considered. The greater the number of nearby or crossing foreign pipeline systems relative to the proposed pipeline, the greater the chance for interference-current activity. This includes both steady-state interference current and transient current exchange between pipelines.

Urban Environments. The potential for damage to the pipeline coating or the pipeline itself from construction activity will usually be much greater in an urban environment. Therefore, the total current requirements for cathodic protection should be generously rated during design to provide for future increases beyond that which would be considered for normal coating degradation.

Adjacent overhead electric circuits can cause induced or conductive couplings between the electric circuit and the pipeline steel. Such couplings, if of sufficient or steady-state magnitude, an result in ac potentials on the pipeline steel that are injurious to personnel, pipeline equipment, or the pipeline dielectric coating. Although not strictly a corrosion consideration, such analysis is usually performed by corrosion/cathodic protection personnel because they are best equipped to make such analyses.

Electrical isolation must be established for those portions of the pipeline system intended for cathodic protection. Electrical isolation of the pipeline segments that will be placed under cathodic protection is required for two reasons. First, it minimizes the total amount of protective current needed to establish overall protection, and second, it enhances the ability of personnel to obtain and interpret field survey data relative to the levels of protection being attained.

The best time to analyze the system for the determination of electrical isolation requirements is during the design phase. This allows required isolation devices to be available for installation during pipeline construction and avoids retrofit requirements. Electrical isolation devices include flange insulation kits, insulating couplings, insulating unions, and other devices that block the flow of tongitudinal current.

Tests stations should be established for conducting electrical field surveys intended to determine the performance of the cathodic protection system. Test stations are devices that are similar to electric junction boxes in which insulated electric wires connected to the pipeline steel are terminated. These flush or aboveground stations permit cathodic protection personnel to analyze electrically the operation of the cathodic protection system.

With regard to electrical isolation equipment, there is economic justification for having such test stations and their pipe-connected test wires installed during pipeline construction before the pipe in the trench is backfilled. The number and type of test stations will usually be determined primarily by the type of pipeline system (transmission, distribution, and so on) and the area in which the pipeline will be located.

Construction Techniques. Corrosion control of a pipeline system is normally accomplished through the synergistic effects of cathodic protection and dielectric coatings. Corrosion cell activity is halted by the application of current components in proper densities at pipe steel exposed to the electrolyte. The coating system reduces, by many orders of magnitude in most cases, the total current output required to achieve full protection. Throughout a pipeline service life of, for example, 25 years, any factor that operates to minimize total current requirements can provide significant benefit in terms of operating costs.

Therefore, the pipeline system operator should use a high-quality coating that is well suited to the conditions and location in which the pipeline will operate. In addition, significant care and attention should be paid to ensure that the integrity of the coating is as close to perfect as possible.

Therefore, the primary corrosion considerations in terms of construction are careful handling and transporting of the pipe from the time the coating is applied to the point at which the pipe is backfilled in place. Extreme care in handling, loading, unloading, burying, and backfilling the pipe are paramount concerns. Most pipeline companies follow the practice of locating holidays in the coating by using a high-voltage detector just before or while the pipe is being lowered into the trench. Any holidays detected in this manner are repaired with techniques appropriate to the type of coating used. The purpose of this method is to optimize coating quality immediately before the coating becomes inaccessible.

Corrosion of Specific Types of Pipelines

Transmission Pipelines. Mitigation of corrosion in onshore transmission pipelines is primarily accomplished by the combination of cathodic protection and dielectric coating systems. The design of such cathodic protection systems is reasonably straightforward, because the corrosion engineer can often predict the distance at which protective current application from a remote anode bed will effectively protect the pipeline in both directions from a current drain point attached to the pipeline steel. The distance of effective full protection can be estimated if the pipeline diameter, steel type, wall thickness, soil characteristics, and general coating quality are known. This is so because a pipeline has an attenuation characteristics to current pickup from the electrolyte and longitudinal flow that is analogous to a leaky electric transmission line.

It is interesting to note that it is possible to protect the pipeline to a greater distance from a given anode location on a larger-diameter pipeline than on a pipeline with a smaller diameter. This is because the resistance of the longitudinal pipe steel current path is lower per unit length in proportion to the pipe diameter.

In establishing anode beds for transmission pipelines, an attempt is usually made to place the anodes at remote earth relative to the pipeline. Remote earth in most soils can be a minimum distance of 60 to 150 m (200 to 500 ft) from the pipeline. The higher the resistivity of the indigenous soil, the farther the anode bed must be from the nearest point on the pipeline to be at remote earth.

A remote earth anode bed placement is desirable because it results in the maximum spread of protective current in each direction from an individual anode bed. On larger-diameter (75 to 90 cm, or 30 to 36 in.) pipelines, corrosion can be controlled on 33 to 66 km (30 to 40 miles) of pipeline, assuming a reasonably satisfactory dielectric coating is in place. Remote anode beds are established in primarily two types of installations: Surface anode beds and deep anode beds.

Surface anode beds are typically installations in which a multiple number of cylindrical anodes 7.5 cm (3 in.) in diameter and 152 cm (60 in.) long are installed vertically to a depth of 4.5 cm (15 ft) at 6-m (20-ft) centers. The individual anodes are connected in parallel to the positive-polarity output terminal of a suitably rated transformer-rectifier unit by an insulated anode header cable.

Deep anode beds are often used where right-of-way, urban buildup in the area, or soil resistivity conditions dictate their necessity. A deep anode is vertical installation in which the individual anodes such as those described above are installed in a vertical array in a 20-cm (8-in.) hole drilled to a depth of 30 to 90 m (100 to 300 ft). The intent with a deep anode is usually to attain a remote earth installation without the necessity of departing a long distance from the pipeline right-of-way or attaining a lower electrical resistance (greater operating efficiency) anode installation by placing the anodes in lower resistivity, subsurface soil horizons.

Where localized protection of discrete areas on a transmission pipeline is required, either properly sized galvanic anode arrays or distributed impressed-current anode systems are usually used. Distributed impressed-current anode systems consist of one or more cylindrical anodes installed relatively close to the pipeline (7 to 30 m, or 25 to 100 ft) such that a modest current discharge from each anode will couple to the exposed pipeline steel in its vicinity.

Distribution Pipelines. Cathodic protection of distribution pipelines is accomplished with the same techniques and system as those cited for transmission pipelines, that is, galvanic anodes or impressed-current systems. However, the installation, surveillance, and maintenance of distribution pipeline cathodic protection systems can be much more complex than with a transmission pipeline, which is often a simple buried, coated steel cylinder running between points A and B.

Distribution pipeline systems are often installed in a grid configuration conforming to the roadways fronting the individual structures that the system services. Whether rural or urban, they are usually in place in commercial areas, often under paved roadways and in close proximity to other buried piping and electrical and telephone systems.

In addition, distribution pipeline systems are multiple delivery points, all of which require the installation and maintenance of electric isolation devices, which are often not in readily accessible locations, such as building basements. Failure or inadvertent short circuiting of just one such electric insulation device, out of a total of perhaps hundreds, can render a well-designed cathodic protection system ineffective.

For this reason, many distribution pipeline operators sectionalize their distribution pipeline systems into discrete areas of electrically continuous piping. This protects against the possibility of one short-circuited isolation device disabling a large portion of the cathodic protection system.

By virtue of the close proximity of a distribution piping system to adjacent buried metallic structures that may not be cathodically protected (for example, cast iron water or sewer systems), inadvertent contacts to such systems can also disable an otherwise effective cathodic protection system. In heavily trafficked urban areas, such contacts can be extremely difficult to locate and to clear. In addition, assessment of the continuing effectiveness of a distribution pipeline cathodic protection system through electrical test techniques is also difficult because the system is usually located under paved surfaces.

Despite all of the difficulties cited above, distribution pipeline systems are protected against corrosion activity. Both galvanic anode and impressed-current systems are used by system operators. The most prevalent type of design is the distributed anode type, often with galvanic anodes installed at specific intervals that are a function of the diameter of the pipeline. Impressed-current systems are also used, but with their typically higher operating voltages and protective current magnitudes, they are more susceptible to interference-current effects from adjacent buried metallic piping systems.

Electrical System Pipe-Type Cables. Pipe-type cables are basically pipelines that are used as buried electrical transmission circuits--usually in urban environments in which aerial rights-of-way are not available. The buried pipe contains three insulated phase conductors and a dielectric medium, such as insulating oil or an inert gas.

The carrier pipe will typically be 20 cm (8 in.) in diameter and have a appropriate dielectric coating similar to conventional pipelines. Unlike conventional pipelines, the pipe-type cable carrier pipe must have connections available to the electric safety grounding system at the electric utility facilities each end of the carrier pipe. This is required to permit ground fault current to flow from a faulted phase conductor(s), thus causing safety relaying devices to operate equipment so as to clear the fault, that is, deenergize the circuit.

The buried carrier pipe is subject to all the sources of corrosion cell activity of any other buried pipeline and therefore will require the application of cathodic protection. It would be possible to cathodically protect the carrier pipe if it were to be solidly connected to the grounding system at both ends. Large amounts of total current would probably be required, however, with the additional possibility of interference-current activity also being a consideration in urban areas.

Two principle systems are used that satisfy the requirement for corrosion control of the carrier pipe while maintaining an electric safety grounding system connection for ground fault protection. They will be discussed below.

Dropping Resistor. This system has both ends of the carrier pipe tied to station ground through large-amperage resistor elements of typically 3 mΩ. Impressed-current rectifiers are mounted at each resistor and operated so as to circulate 100 A through the resistor from the station ground side to the carrier pipe. This current flow creates a voltage drop across the resistor such that the carrier pipe is held at a potential of -0.3 V relative to the potential of the station grounding network.

Polarization Cells. In this system, the carrier pipe is connected to the station grounds through high-amperage non-ohmic resistance cells. Cathodic protection is applied to the carrier pipe as desired. To the low-level dc potentials associated with cathodic protection, the cell appears as an open circuit, and protective current is confined to the carrier pipe.

In the event of a ground fault of one or more phase conductors in the carrier pipe, the increase in potential of the carrier pipe steel causes the polarization cell to go into a low-resistance conductive mode that results in coupling of the carrier pipe to the station ground. This action is analogous to a fast-response lightning arrester with amperage sufficiently great to conduct the anticipated fault current magnitude. When the ground fault is cleared, the cell is restored to an open-circuit mode.

Corrosion in the Mineral Industry

G.A. Minick, A.R. Wilfley & Sons, Inc., Centrifugal Pump Division; D.L. Olson, Center for Welding Research, Colorado School of Mines

Introduction

THE MINING, mineral-processing, and extractive metallurgy industries are concerned with a wide range of corrosive media and must consider material selection as perhaps the most important general approach to corrosion resistance. It is common to find the manganese steel is crushing and grinding service, variations of cast (hard) iron grinding balls and mill liners, hardenable and carburized grades and low-alloy steel gears and geared transmissions mining machinery, steel and carbide tools and drills, high nickel and cobalt hardfacing alloys, stainless steel leaching tanks and pumps, and high nickel-chromium and titanium alloys for the most severe environments. This wide selection of materials and their service lives affect operation cost and productivity. With the increasing mechanization in mines, corrosion problems and material performance become increasingly important to the mining industry.

Corrosion associated with the mining industry can be characterized as electrochemical attack enhanced by abrasion. All ingredients for corrosion attack are available, including highly conductive water, grinding media, dissimilar materials, oxygen, large pH range, and the presence of many well-known corrosive species in solution.

Mine atmospheres and mine waters are unique in that they vary widely from mine to mine. For example, temperatures have been found to range from approximately 5 to 30 °C (40 to 90 °F) in coal mines and above 40 °C (100 °F) in metal mines. Refrigeration and air conditioning have become necessary for improved working conditions. Humidity levels between 90 and 100% are common. Mine water also varies in mineral content, pH, and corrosivity.

Tables 1 and 2 list the contents of some Canadian mine waters. These constituents have been found in mines in the United States and in other countries, although the amounts can vary. Values of pH range from 2.8 (very acidic) to 12.3 (basic). High values are often the result of the lime content of the cement added to backfill. Chlorine ion (Cl^-) values show a wide range (from 5 to 25,000 ppm), and sulfate ion (SO_4^{2-}) values range from 57 to 5100 ppm. Chloride and sulfate are considered to be the most aggressive ions present in mine waters and account for the high corrosivity of most mines.

Table 1 Analyses of some Canadian mine waters

Values have been converted from grams per liter to parts per million.

Mine number[a]	pH	Ionic species present, ppm						Dissolved solids, ppm[b]
		Cl^-	SO_4^{2-}	**Ca^{2+}**	**Mg^{2+}**	HCO_3^-	**Cu^{2+}**	
1a	5.4	20	1080	210	80	<100	2	1740
1b	5.9	60	1380	390	55	<100	1	2290
1c	12.3	40	240	520	0.7	<100	<0.1	2610

Important constituents of dissolved colloidal or suspended matter that contribute to the corrosive environment can be classified as dissolved gases, mineral constituents, organic matter, and microbiological organisms (Ref 3). Dissolved oxygen enhances the corrosion process, especially in waters with low pH, but oxygen content can vary widely in mine waters. Oxygen concentration also decreases with increasing temperature. One example of the effect of oxygen on corrosion rate is that aearation with oxygen has been found to increase grinding ball wear by 13 to 16% (Ref 4).

Carbon dioxide (CO_2) in mine water is associated with carbonate ion (CO_3^{2-}) content. Calcium bicarbonate ($Ca(HCO_3)_2$) has been reported to be the predominant source, and magnesium carbonate ($MgCO_3$) has been found to be a less active secondary source (Ref 3). Carbon dioxide has little effect on corrosion rate except when pH levels are below 7.

Mineral content of mine water begins with the breakdown of iron sulfide minerals, principally pyrite and marcasite, that are generally associated with most mineralization species. Oxidation of pyrite produces sulfuric acid (H_2SO_4). Consequently, mine water with pH as low as 2 is produced. The acid water accelerates the breakdown of minerals, increasing the concentration of silicon (Si^{4+}), aluminum (Al^{3+}), calcium (Ca^{2+}), magnesium (Mg^{2+}), and manganese ions in mine waters.

Anaerobic and aerobic microorganisms are well-known corrosion-producing agents. Principle acid-producing species are *Thiobacillus thio-oxydans*, an aerobic species (Ref 3, 5). Their presence oxidizes sulfur or sulfur compounds, producing H_2SO_4 and contributing to the acidity of mine water.

Another species of aerobic bacteria, *Ferrobacillus ferro-oxydans,* is associated with the *Thiobacillus* type. When both types of bacteria are present, their synergistic effect has been reported to increase H_2SO_4 production by four times as compared to the production rate when no bacteria are present (Ref 6). Acid mine waters produced by these microorganisms can approach very acidic conditions. Anaerobic microorganisms such as *Sporovibrio desulfuricans*, are a sulfate-reducing type and are responsible for rapid corrosion of iron and steel structures (Ref 7). They are found in most soils. As mentioned earlier, they also reduce sulfates and sulfides by using available hydrogen from either organic compounds or aqueous electrolyte at the cathodic interface of metal, producing hydrogen sulfide (H_2S).

High humidity, high ambient temperature, dusts, fumes, breakdown of minerals that form acid mine waters, and microbiological microorganisms all contribute to corrosion and lead to degradation of mining equipment. Examples of the corrosion of principle mining equipment will be discussed below. Table 3 lists some of the various engineering materials that are used for mining and milling equipment.

Table 3 Selection of materials for mining and mill application

Application	Environment	Materials
Crushing and grinding	Heavy pressure, shock-impact loading	Austenitic manganese steels (ASTM A128), AISI 4300 series, ASTM A579 alloy steel, AISI 8600 series
Mill liners, grates, and abrasion-resistant plates	Severe gouging, crushing impact and wear, wet (pH 5-8)	Austenitic manganese steels, martensitic chromium-molybdenum white cast iron, martensitic high-chromium white cast iron, martensitic nickel-chromium white iron, martensitic medium-carbon chromium-molybdenum steel, austenitic 6Mn-1Mo steel, pearlitic high-carbon steel, pearlitic white cast iron
Grinding balls (Ref 8, 9)	Severe gouging, crushing impact and wear, wet (pH 6-8)	Pearlitic white cast iron, martensitic white cast iron, forged (0.8% C) steel, AISI 4155, Ni-Hard type 1, Ni-Hard type 4
Grinding rods (Ref 8, 9)	Severe gouging, crushing impact and wear, wet (pH 6-8)	Heat-treated alloy steel, AISI 52100, hot-rolled AISI 1095 modified with 1.2% Mn, hot-rolled AISI 1095 with 0.4% Mn
Gearing for mining machinery	Wet, lubricated (pH 5-8) wear, light duty	Carburized AISI 1015, 1020, 1022, 1117, 1118, heat-treated AISI 4340, 8645
	Wet, lubricated (pH 5-8) wear, moderate duty	Carburized AISI 8628, 4620, 4615, or equivalent
	Wet, lubricated (pH 5-8) wear, heavy duty	Carburized AISI 4820, 4320, 2320, or equivalent; nitrided AISI 4340, 4140, 4350, and 2.5% Cr steel
Load-haul-dump equipment	Wet (pH 5-8) wear, impact	AISI 1020, cast carbon steel, cast austenitic manganese steels (ASTM A128), cast ASTM A 579 steel, ASTM A514 steel
Percussion drilling tools	Wear, impact, gouging (pH 6-8)	Carburized AISI 4320, 8620, and 9315; quenched-and-tempered 4140
Hardfacing	High-impact, wet (pH 6-8)	Austenitic manganese steels
	Unlubricated metal to metal rolling or sliding	Self-hardened, air-hardened steels
	Highly abrasive conditions, wet (pH 6-8)	High-carbon high-chromium white cast iron, high-chromium white cast iron
	Sliding abrasion on cutting edge of drilling tools, wet (pH 6-8)	Special tungsten- and boron-containing weld deposits
	Abrasion at high temperature and/or corrosion	High-nickel or -cobalt weld deposits
Pumps	pH (0-13), abradants	AISI type 304 or 316 stainless steel, Ni-Hard types 1 and 4, 27% Cr white cast irons
	pH (0-13), abradants	Low-carbon, high-manganese steels
	pH (0-13), abradants	Low-alloy cast iron
	pH (0-13), abradants	ACI CD-4MCu
	pH (0-13), abradants	ACI CF-3M (low carbon for as-welded corrosion resistance)
	pH (0-13), abradants	ACI CN-7M (niobium or titanium for as-welded corrosion resistance)
	pH (0-13), abradants	ASTM A484 steel (low-carbon for as-welded corrosion resistance)
	High-temperature environments	ASTM A743 or A744 nickel-base alloy, grade CZ-100
Flotation cells	Corrosive, pH (0-5)	Ni-Hard type 1, type 316 stainless steel
Paddles	Corrosive, pH (0-5)	Fiberglass-reinforced plastic and rubber
Spirals	Abrasive	Ni-Hard type 1

Classifiers blades	. . .	Ni-Hard type 4
Ore chutes	Impact, gouging, abrasion, pH 6-8	Ni-Hard, nickel-containing manganese steel
Scrapers	Impact loading, gouging, abrasion	Cast ASTM A579 steel, Ni-Hard cast iron, hard cast irons
Wire rope	Corrosive-abrasive, pH 2-12	Kevlar, steel wire rope
Piping	Corrosive-abrasive	Type 316 stainless steel, CN-7M, Ni-Hard cast irons, rubber covered fiberglass-reinforced plastic
Scrubbers	Off-gas products	High-grade nickel alloys
Chain conveyors	Corrosive-abrasive	Plated (nickel, cadmium, or zinc) steels

Wire Rope

Mine shaft depths of 1830 m (6000 ft) are not uncommon; gold mines in South Africa approach depths of 2285 m (7500 ft) (Ref 10). The hoisting equipment used in these mines, especially ropes, on which lives of personnel depend, is subjected to the corrosive environment of the mines. Although wear is also a factor, corrosion is perhaps the most serious aspect of mine safety. Corrosion is difficult to evaluate and is a more serious cause of degradation than abrasion (Ref 11). If corrosion is evident, the remaining strength cannot be calculated with safety, nor is there any reasonable way to determine whether or not the rope is safe except by the judgement of the inspector.

Statistical analysis from the results of rope tests on mine-hoist wire ropes has shown that 66% of the ropes exhibited the greatest strength loss in the half of the ropes nearest the conveyance (Ref 12). This is the portion of the rope that is in contact with the shaft environment during most of its service life.

Replacement of hoist rope is a routine procedure in most mines and is suggested every 18 to 36 months, depending on the mine environment and use (Ref 1, 13). Some regulatory agencies will not allow the use of a shaft rope on which marked corrosion is evident (Ref 11).

Adequate service life of hoist rope is economically desirable. Therefore, the composition of present-day hoist rope has been extensively studied. Carbon steel strand wire has competition from such substitute materials as stainless steel (Ref 14) and synthetic fibers (Ref 15). Austenitic stainless steel rope (15.5 to 18.5% Cr and 11 to 13% Ni) is available and has endurance strength of 72 to 83% of that of carbon steel wire. Much can be said for synthetic fiber rope construction. For example, Aramid fiber rope has exceptional strength-to-weight ratios, outstanding tension-tension-fatigue performance (Ref 15), and excellent corrosion resistance.

Roof Bolts

Roof bolts are extensively used for roof support in underground mines. More than 120 million roof bolts are used per year in the United States mining industry (Ref 11). Roof bolts made of low-carbon steel in a number of design variations are subject to corrosion attack in the mine environment. In sulfide mines, the roof bolts have been reported to fail within 1 year by breaking at a distance of approximately 355 mm (14 in.) inside the drill hole (Ref 1). This roof bolt failure has been related to stress-corrosion cracking. Roof falls are associated with such roof bolt failures.

Pump and Piping Systems

Corrosion in pump and piping systems is well known in the mining and mineral-processing industries. The first indication of pump corrosion is that the pump no longer meets the flow demands of capacity and head requirements. Also, the external surfaces are corroded and encrusted with corrosion product.

Because recognition of corrosion type is so important in diagnosing corrosion problems and their prevention and because published information on case histories is scarce, corrosion types will be discussed and illustrated in the following sections in this article.

Uniform Corrosion. The most common form of pump corrosion is characterized by uniform attack on the entire exposed surface. Figure 1 shows uniform corrosion on a stainless steel pump impeller that was exposed to 50% phosphoric acid (H_3PO_4) and 10% gypsum pumping fluid for approximately 1 year. Figure 2 shows uniform corrosion due to potash brine on a cast (hard) iron pump runner.

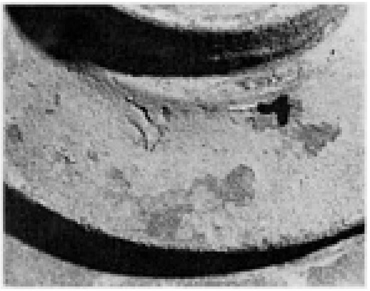

Fig. 1 Uniform corrosion of ACI CD-4MCu cast stainless steel pump impeller after 1 year in an environment containing 50% H_3PO_4 and 10% gypsum. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

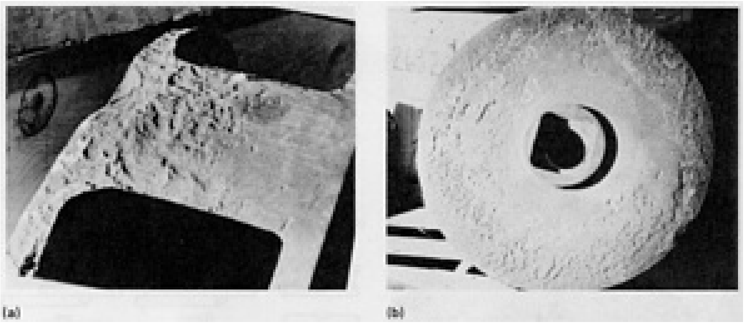

Fig. 2 Uniform corrosion of an abrasion-resistant iron pump runner that contacted potash brine slurry. (a) End view. (b) Side view. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

Pitting corrosion on an Alloy Casting Institute (ACI) CF-8M stainless steel casting pump case is illustrated in Fig. 3. This pump case, which was exposed to low pH and high Cl^- concentration, failed after approximately 3 years of service.

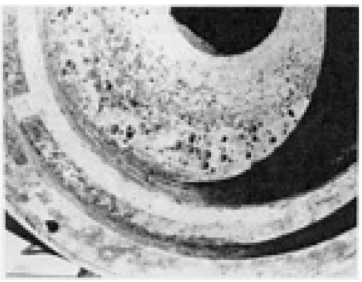

Fig. 3 Pitting corrosion of an ACI CF-8M stainless steel pump case used to pump a nickel plating solution with a high concentration of Cl^- and a high operating temperature. This damage occurred during 3 years of service. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

Erosion-corrosion of an ACI CN-7M stainless steel cast impeller after exposure to hot concentrated H_2SO_4 with solids present is shown in Fig. 4. Erosion-corrosion is evident in Fig. 5, which shows that the erosion-corrosion damage increased on the portion of the impeller that had the greatest fluid velocity. This impeller, cast from an abrasion-resistant while iron, was used to pump fluids containing 30% solid (iron ore tailings) at a pH of 11.2.

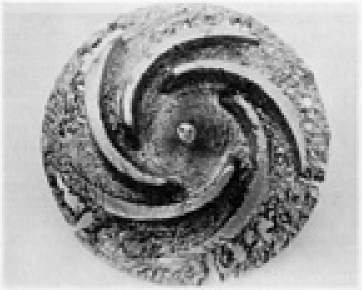

Fig. 4 Erosion-corrosion of ACI CN-7M stainless steel pump components that pumped hot H_2SO_4 with some solids present. Note the grooves, gullies, waves, and valleys common to erosion-corrosion damage. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

Fig. 5 Erosion-corrosion of an abrasion-resistant iron pump runner used to pump 30% iron tailings in a fluid with a pH of 11.2. This runner had a service life of approximately 3 months. Note that most of the damage is on the outer peripheral area of the runner where fluid velocity is the highest. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

Crevice Corrosion. Figure 6 shows crevice corrosion on an ACI CF-8M cast stainless steel pump case that was gasket sealed on the discharge flange. Attack is evident in the region where the gasket was placed. It is important to design mining and milling equipment for easy drainage and cleaning in order to prevent the buildup of stagnant water that will produce concentration cells and lead to crevice corrosion and pitting. Figure 7 illustrates both poor and improved design

for avoidance of localized attack. More information on proper design is available in the article “Designing to Minimize Corrosion” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook.*

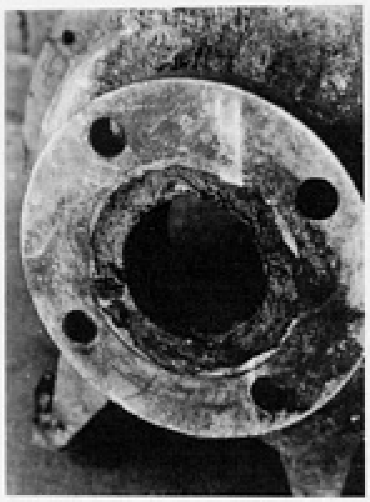

Fig. 6 Crevice corrosion at the intake flange of an ACI CF-8M stainless steel pump case. Notice that the corrosion damage occurred under the gasket. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

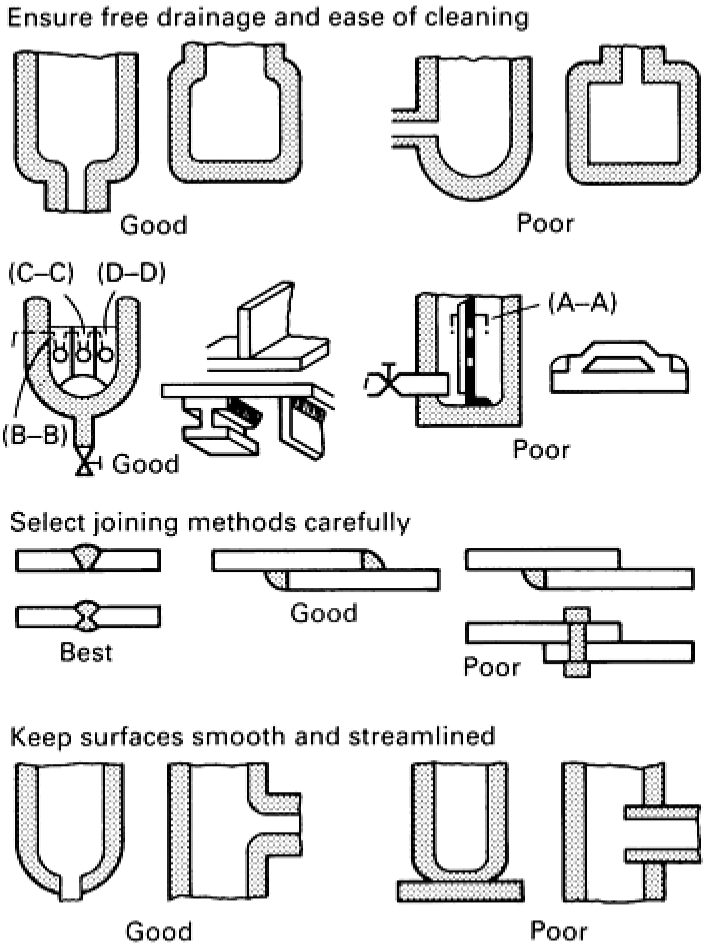

Fig. 7 Poor and improved engineering design to avoid crevice corrosion. Source: Ref 16

Intergranular corrosion is common to stainless steel pump castings. Figure 8 shows the excessively attacked grain boundaries. A quick test to identify this type of corrosion is to peen the pump casting with a small hammer. Loss of acoustical properties is evidence of intergranular grain-boundary attack, especially in sensitized stainless steel castings. A form of intergranular corrosion associated with weld deposits that is commonly called weld decay is shown in Fig. 9, which illustrates a field-weld repair of an ACI CN-7M stainless steel impeller that was not postweld heat treated (solution annealed and quenched) to restore corrosion resistance. This weld-repaired casting was exposed to a phosphoric anhydride (P_2O_5) solution at 80 °C (175 °F). It is evident that the weld decay occurred in the heat-affected zone of the weld deposit.

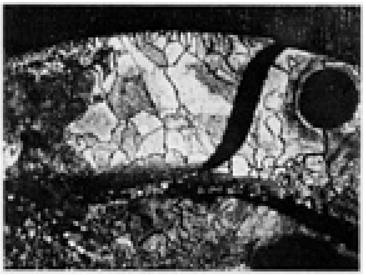

Fig. 8 Intergranular corrosion of an ACI CN-7M stainless steel pump component that contacted $HCl-Cl_2$ gas fumes. Note the grain-boundary attack. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

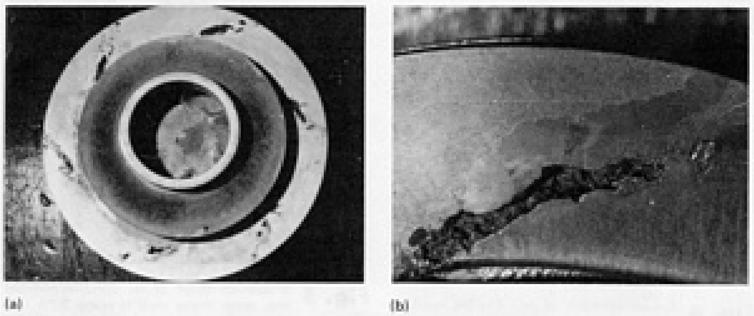

Fig. 9 Weld decay of an ACI CN-7M stainless steel pump impeller that was field weld repaired with no postweld heat treatment. The pump service was P_2O_5 solution at 80 °C (175 °F). (a) Overall view of impeller. (b) Closeup view of the weld repair and the associated weld decay, which occurred adjacent to the weld deposit. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

Dealloying. Figure 10 shows selective leaching (dealloying) of a high-nickel cast iron. The physical dimension of the pump component remained constant, while porous, selectively leached regions grew into the casting. This porous layer consists of residual graphite contained in the cast iron and corrosion product. This pump component was exposed to fluosilicic acid (H_2SiF_6) and failed after 12 days of service.

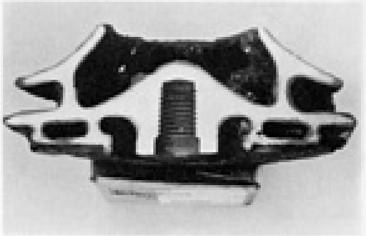

Fig. 10 Selective leaching of a cast iron pump impeller after 12 days of service in H_2SiF_6. Section through the impeller shows the selectively leached layer, which contains graphite and corrosion product. Courtesy of A.R.

Galvanic corrosion between two stainless steels is illustrated in Fig. 11. These AISI type 304 stainless steel stud bolts held together an Alloy 20 (ACI CN-7M) pump housing. The bolts became anodic to the housing in 45% H_2SO_4 and subsequently failed. Table 4 lists various combinations of pump an valve trim materials and indicates the combination that may be susceptible to galvanic attack.

Table 4 Galvanic compatibility of materials used for pump components

Body material	Trim		
	Brass or bronze	**Nickel-copper alloy**	**Type 316**
Cast iron	Protected	Protected	Protected
Austenitic nickel cast iron	Protected	Protected	Protected
M or G bronze 70-30 copper nickel	May vary[(a)]	Protected	Protected
Nickel-copper alloy	Unsatisfactory	Neutral	May vary [(b)]
Alloy 20	Unsatisfactory	Neutral	May vary [(b)]

(a) Bronze trim commonly used. Trim may become anodic to body if velocity and turbulence keep stable protective film from forming on seat.

(b) Type 316 is so close to nickel-copper alloy in potential that it does not receive enough cathodic protection to protect it from pitting under low-velocity and crevice conditions.

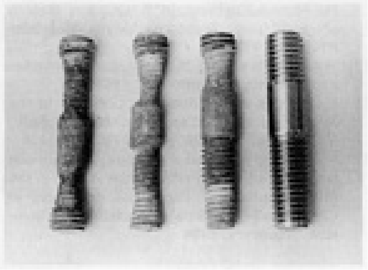

Fig. 11 Galvanic corrosion of AISI type 304 stainless steel stud bolts that fastened two Alloy 20 (ACI CN-7M) pump components. The pump was pumping 45% H_2SO_4 at 95 °C (200 °F). The stud bolts were anodic to the Alloy 20 pump housings. Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

Cavitation is a familiar term within the industry. The causes are also familiar; principally, there is a lack of net positive suction head, which is the suction pressure that should be available to the pump for correct performance. Cavitation usually manifest itself by another familiar pump characteristic--noise. The buildup and subsequent collapse of bubbles on the impeller create the familiar popcorn noise.

The effects of cavitation (the violent collapse of bubbles) are illustrated in Fig. 12 and 13. Plastic and metal impellers have been found to be susceptible to cavitation damage. A contributing cause of cavitation has been found to be plugged filters on the intake (suction)side of the pump, coupled with the marginal net positive suction head available to the pump. Table 5 lists engineering materials based on their resistance to cavitation damage.

Table 5 Rating of materials for cavitation resistance

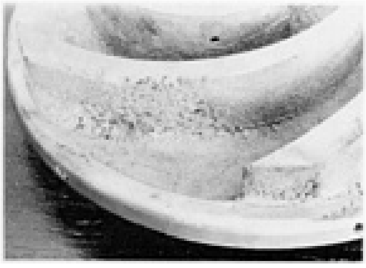

Fig. 13 Cavitation damage of an ACI CN-7M stainless steel pump impeller that pumped NH_4NO_3 solution at 140 °C (280 °F). Courtesy of A.R. Wilfley & Sons, Inc., Pump Division

Figure 12 shows the craterlike damage caused by cavitation on a plastic impeller. Figure 13 shows cavitation damage on an ACI CN-7M stainless steel impeller that pumped hot ammonium nitrate (NH_4NO_3); the pumping installation had a total lack of a net positive suction head.

Erosion-Corrosion. During mill processing, fluids are pumped containing particulates that are usually carried in a corrosive medium. Pumping this slurry promotes erosion-corrosion in piping, tanks, and pumps. Erosion-corrosion is a

function of the fluid velocity and the nature of the particulates and fluid. The following procedures can be used to reduce erosion-corrosion or to increase the service lives of piping and pumping systems:

- Increase the thickness of pipes
- Use larger inside diameter pipes to reduce fluid velocity for the transport of a specific fluid volume
- Streamline bends in piping to ensure laminar flow
- Use nonmetallic ferrules inserted in the inlet ends of pipes
- Design for easy replacement of parts that experience severe erosion-corrosion
- Use coatings that produce an erosion-corrosion resistant barrier, such as rubber coatings (Ref 18)

Material selection is an important consideration for erosion-corrosion resistance. Alloy hardness has also been shown to be a factor in erosion-corrosion resistance. Generally, soft alloys are more susceptible to erosion-corrosion than their harder counterparts, but the relative hardness properties of the alloy can be misleading, because the hardening mechanism affects resistance to erosion-corrosion (Ref 8). For example solid-solution hardening has been found to offer greater resistance than that provided by conventional heat treatment. One example of this is the cast precipitation-hardening alloy ACI CD-4MCu, which outperforms Alloy 20 (CN-7M) and austenitic stainless steels in many applications.

Economics often enters into material selection. Cast iron is relatively more economical and frequently exhibits better erosion-corrosion resistance than cast steel. High-silicon cast iron (14.5% Si) has been found to be an economical selection.

Active-passive materials, such as stainless steels and titanium, owe their corrosion resistance to their developing a protective passive oxide film. This protective film, however, can be continuously damaged by erosive-abrasive processes. Selection of passive alloys should be based only on experience and/or laboratory test results.

Joints must be reliable. Welded pipe, such as carbon steel or stainless steel, is free of flanges but is costly to install. Nonwelded joints are susceptible to crevice corrosion; therefore, stainless steel, in particular, will not attain its expected service life.

Tanks

Most tanks are made from low-carbon steel for economic considerations. The most common corrosion protection for these tanks is the use of coatings and linings. Cathodic protection can also be used and in commonly employed in conjunction with a coating (Ref 18). Coating materials can be classified as cement, epoxy, epoxy-phenolic, neoprene, latex, sprayed polyresin coating, polyesters and vinyl esters (heavy coatings), and baked phenolic. Steel tanks are also lined with natural rubber, synthetic elastomers, rubber-backed polypropylene, and glass. Glass lining would require an oven bake.

Stainless steel and titanium alloys have also been used for tanks. Their use depends on their specific corrosion resistance to the solution. Selection of an alloy type becomes a question of economics.

Reactor Vessels

A variety of materials are used, depending on the corrosivity of the media being contained. With neutral or alkaline pH, carbon steels are often used. With increasing corrosivity, consideration is first given the austenitic stainless steels, then iron-nickel-chromium superalloys, and finally nickel-base superalloys. For special environments, copper, copper-nickel, and nickel-copper (Monel-type) alloys are used (Ref 19). Titanium is known to have excellent corrosion resistance in some of the most aggressive solutions.

Cyclic Loading Machinery

The mining and mineral industry use large numbers of rotary and cyclic loaded equipment. This equipment is subject to fatigue and corrosion fatigue. Table 6 illustrates the significant reduction of fatigue strength of various materials that were tested in mine water and compared to fatigue strength in air. This problem can be reduced by designing heavier sections into the part to reduce load and by applying protective coatings (Ref 18).

Table 6 Fatigue and corrosion fatigue strengths of various alloys at 10^7 cycles

Metal	Fatigue strength		Corrosion fatigue strength					
			In Levack water		**In Helen water**		**In Leitch water**

Corrosion in Structures

John E. Slater, Invetech, Inc.

Introduction

THE PREVENTION of metallic corrosion in structures, particularly the consideration of its effects in initial design and fabrication or later during in-service inspection and retrofit, is vital in ensuring the expected longevity of the structure. Indeed, in many cases, structures may have to last well beyond their originally anticipated lifetimes--for example, the extended lives of structures in Europe that contain metal, some of which date back many hundreds of years.

In considering the ramifications of corrosion and its prevention in different types of structures, it is useful to group such structures into various categories. Thus, the modern high rise--whether an office building, an apartment building, a condominium structure, or a special-purpose building such as hospital--poses particular problems related to the corrosion of major structural components (which may be either totally metallic or may contain metallic material) and creates the necessity for corrosion considerations in any connector assembly used to tie the curtain-wall system on the building back to the structural frame or to the backup wall system. In low-rise structures, similar concerns exist, but may be less critical when the structure is only a few stories high.

Under such circumstances, the possibility of danger to people and property resulting from failure of, for example, curtain-wall tie systems may be less. Nevertheless, failure of metallic materials within structure may lead to unsightliness or to possible lack of weathertight behavior. Both may require extensive reworking of the structure to reestablish adequate building performance.

Parking structures are frequently of conventionally reinforced concrete or prestressed/posttensioned construction. Where such structures are in the snow belt areas of the country or where chloride may intrude because of the proximity of marine environments, the reinforcement may be at risk from corrosion. Stadiums are another example in which either steel-frame or concrete-frame approaches can be used. In these cases, certain approaches may be needed to ensure structural integrity, particularly in view of the safety of the many thousands of people who may visit the structure and fill it to capacity.

Bridges have received much attention with regard to corrosion. This has been particularly prevalent in the snow belt states, where deicing salt application has led to significant premature deterioration of decks and supporting structures. However, supporting structures have also suffered damage because of saline water intrusion, particularly in the splash zone of reinforced concrete structures. Also, the use of the weathering steels can be a problem in such structures, especially where design or construction practice does not adequately account for the particular limitations in the use of this type of steel.

Other specialized structures in which specific corrosion conditions may be a concern include sewage plants, which may have isolated situations related to contaminated water and the use of treatment chemicals. Other buildings or structures can be used to house or support chemical plants and/or utility plants. In the latter case, specific aspects of corrosion prevention in nuclear plants--especially containment buildings--have been the subject of critical review. Because many nuclear containment vessels are designed with posttensioned concrete, the longevity of any corrosion protection system applied to the posttensioning tendons is critical. This article will not address specific interactions with manufactured industrial chemicals, because this area is more reasonably the province of general or specific knowledge related to the particular chemical to which the building material will be exposed.

Metal/Environment Interactions

The most common metallic material used in structures is low- or medium-carbon steel. Specialized or strengthened materials, including heat-treated steels, stainless steels, and nonferrous metals, are sometimes employed; use of these materials is the exception rather than the rule (they will be discussed when appropriate in this article). The specific interactions that will be considered are the reactions of steel with the atmosphere in all of its forms--including polluted atmospheres, interior atmospheres, and internal atmospheres (for example, in a cavity wall)--in which the major criteria determining the performance of unprotected metal include the corrosivity of the atmosphere, the temperature, and the time of wetness of the metal.

A major research effort over the past 20 years has been expended in determining the reaction of steel with cementitious materials, which include mortar, concrete, and their variants. The chemical that typically controls corrosion behavior under these circumstances is the calcium hydroxide ($Ca(OH)_2$) introduced into the cementitious material by the portland cement or, in the case of mortars, lime. The reaction of $Ca(OH)_2$) with atmospheric carbon dioxide (CO_2) is an important degradation mechanism that will radically change the behavior of steel that is in contact with or embedded in the cementitious material. The other major factor that influences the corrosion of steel in this environment is the introduction of chloride ion (Cl^-) into the cementitious material. Chloride may play a decisive role in causing the cementitious material to change from a protective to a nonprotective environment with regard to embedded steel.

This article will discuss the generic situation of metallic materials--specifically steel--in reacting with the environments found in structures. These environments will be discussed in specific terms, particularly as related to atmospheric conditions and cementitious environments. The utility of different corrosion protection methods will be described in relationship to particular structures and to the different environments, either atmospheric or cementitious, encountered by the steel. Finally, examples of problems that have arisen in the corrosion performance of metallic materials in these environments will be delineated, with particular attention paid to the different problems as they relate to different structures in which the metallic material may exist.

General Considerations in the Corrosion of Structures

Corrosion of Steel in the Atmosphere. Atmospheric corrosion is discussed at length elsewhere (see the article "Corrosion of Carbon Steels" in this Volume and "Atmospheric Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*). However, a brief discussion of factors affecting such behavior in structures is necessary. Steel corrosion in the atmosphere is typically a function of temperature, humidity, and the presence in the atmosphere of components that increase the corrosivity of the environment. The temperature/humidity ratio is particularly important, because the interaction among these factors leads to a function known as the time of wetness, during which a film of liquid is present on the surface of the steel. Corrosion occurs by a typical aqueous corrosion mechanism during the time that this film is present on the steel surface. The thinner the film, the easier the diffusion of oxygen through the film that drives the corrosion reaction.

The presence of agents in the atmosphere that can dissolve in the liquid film and promote or inhibit its production by changing the dew point can markedly influence the corrosion behavior of the steel. Thus, the presence of pollutants in the atmosphere--particularly sulfur dioxide (SO_2) and related compounds, which can lead to so-called acid rain--will influence the corrosion behavior of the steel by acting several ways, such as:

- An increase in the conductivity, and therefore the corrosivity, of the liquid film
- Changes in the relative humidity at which the film may form
- Influence of the dissolved constituent on the formation and protectiveness of any corrosion product

films that may exist on the steel.

Therefore, the corrosion behavior of steel used in structures can be expected to be a function of the geographical location, which in turn will influence the temperature, humidity, and degree of pollution that exists. This behavior is indicated in Table 1.

Table 1 Corrosion rates of carbon steel calibrating specimens at various locations

Location	Type of environment	Corrosion rate	
		μm/yr	**mils/yr**

Source: Ref 1

Corrosion in marine environments is a specialized subset of atmospheric corrosion. This is because of the influence of wind-blown or particulate sea salt that may contact exposed steel. Sea salt is particularly aggressive to steel, possibly because of the concentration of magnesium chloride ($MgCl_2$) it contains. Therefore, chloride from the major constituent of sea salt, sodium chloride (NaCl), is deleterious to the corrosion behavior of steel because of its effect on the conductivity of the liquid film and its destruction of protective corrosion product films, but $MgCl_2$ acts to acidify the liquid film and, by its deliquescent action, to increase the time of wetness. This is the primary reason why the corrosion rates of structures in marine environments are considerably higher than in any other type of location. Of course, the possibility of splash zone action on the corrosion of structures is beyond the scope of this article (see the article "Marine Corrosion" in this Volume). The dramatic increase in the corrosion rates of steel in marine locations is indicated in Table 1.

Specialized environments exist in which specific pollutants are present as a function of the particular use or location of the structure. Therefore, chemical plant and refinery buildings and structures may be particularly vulnerable to certain types of atmospheric pollutants produced by the processes occurring within the plant and may require particular protective measures. Again, this is beyond the scope of this article, and the reaction of steel to such environments is best determined by noting the effect of the pollutant on the corrosion of steel in such publications as Ref 2.

The atmosphere within closed structures will usually be very different from that on the external surfaces: In general, the presence of pollutants may be significantly reduced, and the control of temperature and humidity may mean that the overall environmental corrosivity is significantly lower than that on the outside surfaces. However, there can be action that affects this circumstance. For example, the well-known barrier effect of internal walls, which is related to their containment of the internal environment, may be breached at certain locations, with the result that air may escape from the interior of the building into the cavity. If structural or other steel is present in this cavity, the interaction of the steel with air, which may be deliberately humidified, in contact with a possibly cold surface can lead to condensation and subsequent corrosion problems that would otherwise be unanticipated.

Such problems have been noted in the past--not only from the viewpoint of structural steel framing but also from the possibility of corrosion of elements in the system that tie the external cladding back to the frame of the building. This will be discussed in more detail later in this article. Therefore, concern is necessary not only for the influence of the external environment on the corrosion of steel but also for the effects of the internal environment, particularly the lack of containment.

Fireproofing is often mandated by fire codes for structural steelwork within buildings. In the past, fireproofing was used that contained corrosive constituents. Under circumstances in which moisture levels at the structural steel may increase (because of the exfiltration of humid air or the infiltration of water), the corrosive constituent in the fireproofing can lead to unacceptable corrosion of the steel. This potential problem is addressed in ASTM E 937, which is a standardized test for determining the corrosivity of such materials under standardized conditions (Ref 3). The use of coatings that meet conditions related to this test is required by many codes and should be mandated by the specifying architect or engineer.

Whenever steel is used in buildings, there is always the possibility that galvanic contact may occur. Therefore, galvanized conduit may contact bare steel. Copper-base alloys are used as wiring--for example, lightning conduction rods. In general, the relative positions in the galvanic series of metals in seawater will normally dictate whether or not there is a potentially significant problem with galvanic corrosion when structural elements are in contact. The environment surrounding the potential galvanic couple will have a significant effect; more severely corrosive environments allow more galvanic activity to occur. Therefore, unanticipated contact between different metals and the impact of such contact on corrosion behavior must be an ever-present concern.

Although the use of the lower-strength steels generally indicates that environmental/mechanical interactions leading to unexpected brittle failure are very unlikely to occur in the normal environments used in structures, the use of higher-strength steels (particularly those of the quenched-and-tempered variety) may increase the likelihood of such stress-corrosion or hydrogen embrittlement failures, especially in more aggressive environments such as marine conditions. Compounding the problem is the welding that may be performed--for example, on bridge structures. Therefore, quenched-and-tempered steels of the ASTM A709, grade 100, type, which have yield strengths in the 690-MPa (100-ksi) range, must be welded carefully so as, not to create hard regions in heat-affected zones that may be susceptible to hydrogen embrittlement in corrosive environments.

Similar considerations pertain to the area of embedded posttensioning steels. These steels are typically of the cold-drawn type (not quenched and tempered), corresponding to such standards as A416, grade 270 (1860 MPa, or 270 ksi, minimum ultimate tensile strength for seven-wire strand), and A421 (1655 MPa, or 240 ksi, minimum ultimate tensile strength for 6.4-mm, or $\frac{1}{4}$-in., diam wire). Although laboratory test data indicate that cold-drawn steels are considerably less susceptible to failure by hydrogen embrittlement than their quenched-and-tempered counterparts, care must be taken to minimize the aqueous and/or atmospheric corrosion of such steels before and after concrete placement.

With regard to this aspect, the atmospheric corrosion of other metallic materials commonly used in structures is of less concern. Aluminum can be used for a variety of building components, including windows and door frames. If the aluminum is protected from direct contact with uncured mortar or concrete and if a commonly used anodized coating is specified, little atmospheric corrosion is noted except under severe marine conditions. Zinc is typically used only as a protective coating for steel, and as such, the corrosion behavior will be covered in a later section in this article.

Steel in Cementitious Materials. The behavior of steel in contact with cementitious materials (concrete and mortar) is generally governed by the properties of the portland cement that is a constituent of the mortar or concrete. Portland cement is an alkaline material; the alkalinity results from the presence of $Ca(OH)_2$ and other soluble alkali salts. The pH of a saturated $Ca(OH)_2$ solution is approximately 12.5. Reference to the Pourbaix (potential-pH) diagram for iron (Fig. 1) shows that, under these circumstances and in the presence of moisture and oxygen, the steel will be in a passivated condition because of the formation of a thin film of oxide--generally considered to be γFeOOH.

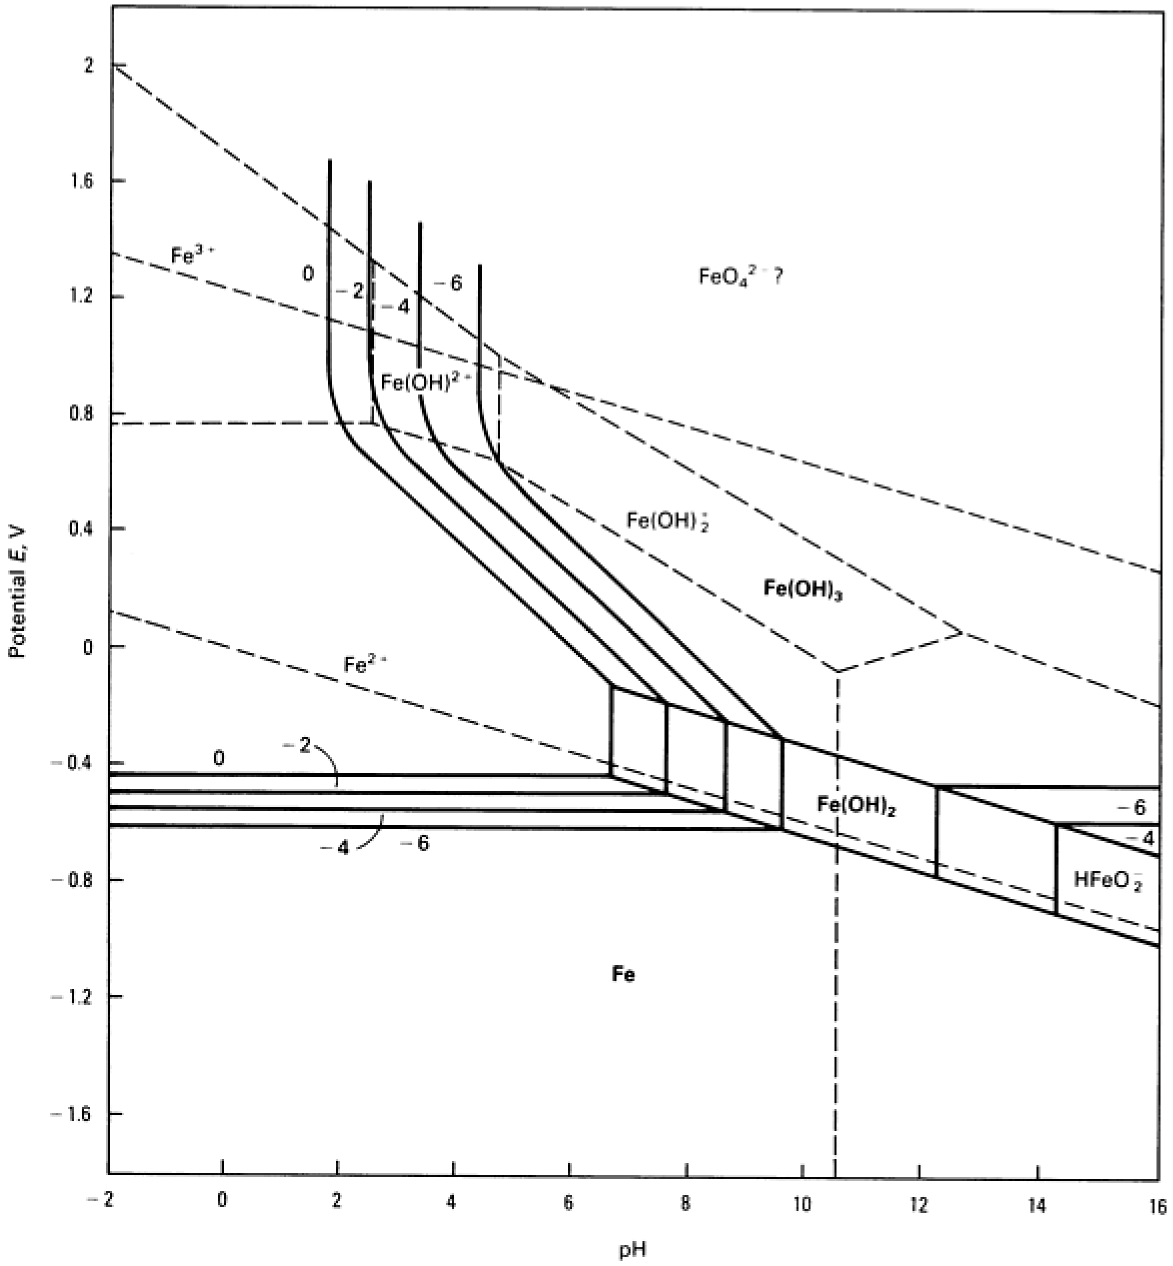

Fig. 1 Pourbaix (potential-pH) diagram for the system iron-water at 25 °C (75 °F). Source: Ref 4

The effect of pH on the corrosion rate of steel in aerated water is shown in Fig. 2. If the oxygen is depleted of if the cementitious material is allowed to dry significantly, then the passive film may well be disrupted. However, under these conditions, the corrosion rate is expected to be extremely low because of the high resistivity and low driving force for the reaction. As will be discussed later in this article, there are various pollutants to the cementitious environment that can modify this behavior, leading to significant corrosion of steel in contact with cementitious materials.

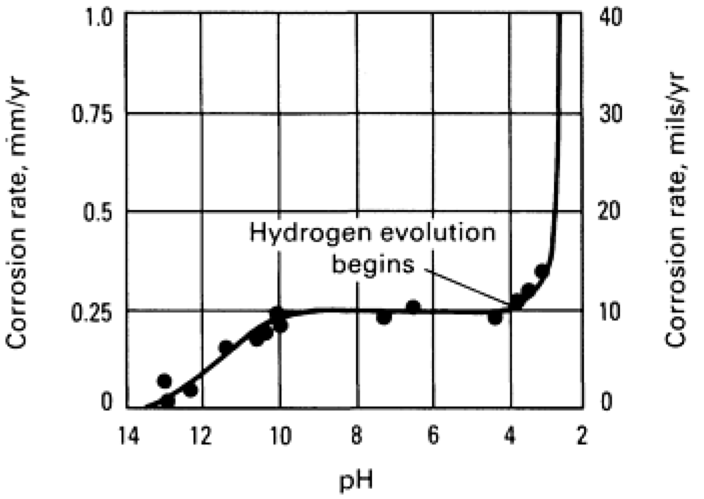

Fig. 2 Effect of pH on the corrosion rate of iron in aerated soft water at room temperature

Concrete is a hard, dense material that consists of cement paste surrounding aggregate particles. The major difference between mortar and concrete is in the size of the aggregate. Concrete contains a high proportion of large aggregate, such as gravel and crushed rock. Steel that is embedded in concrete, generally as reinforcement, can be of two main types. In conventional reinforced concrete, reinforcing bars are used to support the tensile loading, because of the relative weakness of unreinforced concrete in tension versus its significant strength in compression. Such reinforcement will be sized and placed according to requirements determined by the structural engineer. Bar sizes are usually stated as number X, where X represents the numerator in a fraction of eighths.

Other types of reinforcement in concrete are deliberately stressed in tension to place the concrete into residual compression. For prestressed concrete, this is typically accomplished by placing the stressed steel into the concrete form and pouring the concrete around the steel. Once the concrete has cured, then the external tension on the steel is released. The bond between the steel and the concrete, however, now places the surrounding concrete into compression, leading to the well-known concept of prefabricated, prestressed concrete.

Another method of accomplishing this same effect is posttensioning, in which the unstressed steel is placed in the concrete form before the concrete is poured. The steel is typically prevented from developing a bond with the concrete during the pouring process. After pouring and curing of the concrete, the steel now embedded in (but separated from) the concrete is tensioned by a variety of mechanisms, and the tensioned steel is then anchored to the ends of the concrete structure. In this way, the concrete around the steel is placed into tension.

Other steel components that may be embedded in concrete include such items as water lines (which may typically be galvanized steel) and the forms used as containment during the concrete pouring process. In many cases, these forms can be removed; in others, the forms will remain in place, As such, the forms are exposed to the atmosphere on their outer surface and to the concrete environment on their inner surface. The problems that have occurred during the use of such forms, particularly where additives to the concrete have caused a corrosive situation to occur, will be discussed later in this article.

In other cases, unanticipated contact may occur between different materials and steel embedded in concrete. Aluminum can be used for various articles embedded in or located on concrete--for example, balustrades and lampposts. If contact can occur between embedded steel and such aluminum in environments that increase the corrosivity of the steel, as will be determined later in this article, accelerated corrosion of the aluminum can occur, with corresponding galvanic protection of the steel. Although it is conceivable that, for example, copper water pipes may contact embedded steel reinforcement, there are no recognized instances of problems resulting from such contact.

The use of mortar, which is a cementitious material, is a necessary factor in the construction of brick masonry, and steel is used in such masonry in a variety of applications. The use of steel joint reinforcement to enhance the strength of the masonry by placing a mesh or ladder-type system within the bed joint is a common occurrence. Such a system can also be

used to connect two wythes of masonry. The use of ties or anchors to anchor masonry used as a curtain-wall system back to the building frame or to a supporting structure is also necessary. Typical reinforcements, ties, and anchors are shown in Fig. 3. In these cases, although bare steel would suffice in uncontaminated high-pH mortar, it is common practice to use a more corrosion-resistant material for reasons that will be discussed later. Typically, galvanizing is recommended and used--either hot-dip or electroplated.

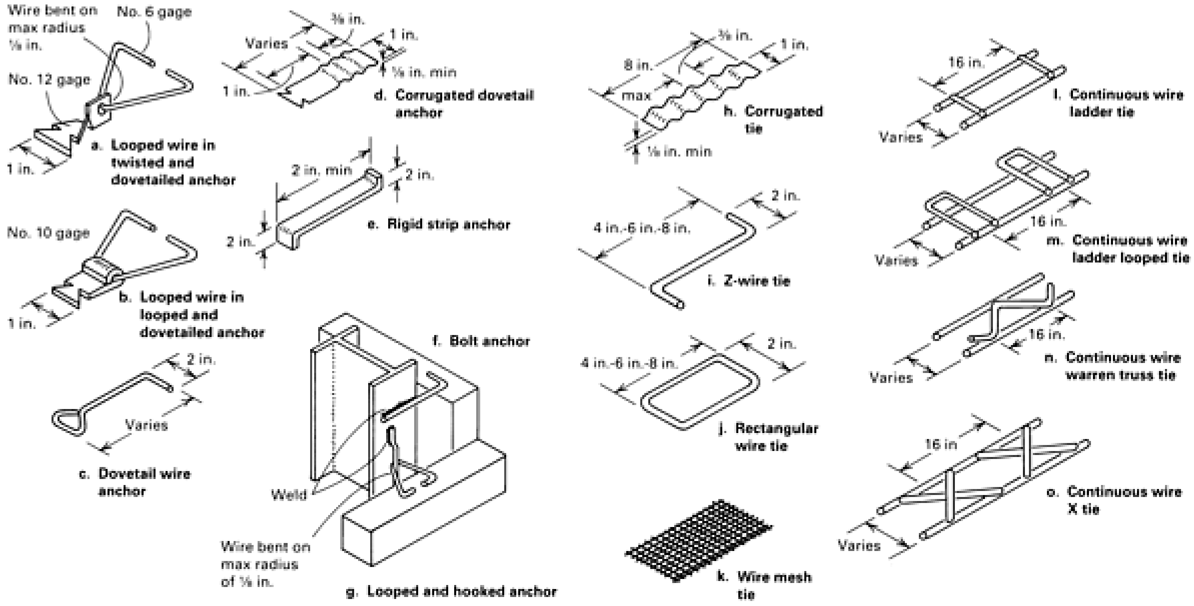

Fig. 3 Typical metallic anchors (a to g) and ties (h to o) used in masonry walls

Other metallic components that may contact mortar include window frames and doorways. These may be steel or aluminum, if metallic. Such steel components can be protected against atmospheric corrosion with organic coatings, but in other cases, metallic coatings, such as galvanizing, can be used. Aluminum components can corrode in the uncured or green mortar environment, but in the absence of further corrosion enhancers, the corrosion rate normally drops to a very low level once curing has occurred and the mortar dries.

The behavior of steel in concrete and mortar as it is influenced by high pH can be drastically altered by two primary factors. The first is carbonation, or the reaction of the $Ca(OH)_2$ with CO_2 from the air. The reaction to form calcium carbonate ($CaCO_3$) lowers the pH of the cementitious material; under these conditions, the steel is no longer passive, but can become active and corrode significantly. This process of carbonation is a function of the porosity of the concrete or mortar, which is a function of such factors as the water/cement ratio, placement adequacy, and vibration/consolidation. In general, however, mortar is much more permeable than concrete and carbonates much more rapidly. Under these circumstances, the mortar in masonry structures must be considered to undergo carbonation at a relatively early point in its life. To prevent the corrosion of embedded steel due to carbonation, it is common practice to use protective coatings on steels (as has already been discussed, galvanizing is common) or to use inherently corrosion-resistant materials, such as stainless steels.

The second major contributor to the corrosion of embedded steel in cementitious materials is the influence of chloride. Chloride in sufficient quantities prevents the formation of the initial protective oxide film on steel (if the chloride is present in the material mix during the curing process) or, if added later, breaks down the passive film and allows corrosion to proceed by a mechanism similar to the pitting of stainless steel passive films by chloride.

Possible chloride sources in the mixing process are the aggregate, chloride introduced with the mixing water (a problem frequently encountered in the Middle East, where brackish water is often the only water available), and chloride-containing admixtures deliberately added to the mix as a set accelerant or so-called antifreeze--most commonly calcium chloride ($CaCl_2$). Chloride can also find its way into the cementitious material after placement and curing, because of the application of chloride to the outer surface. Sources of such chloride are marine environments. Deicing salt placed onto concrete bridge decks, parking structures, and so on, may also find its way onto buildings as a result of splash from

roadways. Another possible source for chloride in mortar is the absorption of hydrochloric acid washing solutions applied to the masonry surface.

The quantity of chloride necessary to cause corrosion of bare steel in uncarbonated cementitious systems depends initially on the stage at which the chloride is introduced. For bare steel in initially chloride-free concrete that is subjected to chloride infiltration from the external surface, corrosion has been found to initiate on the steel when the chloride level reaches between 0.02 and 0.04% by weight of concrete at the steel interface. When the chloride is present in the mix, the tricalcium aluminate of the concrete can insolubilize a certain portion of the chloride during the curing process. Recognition of this fact initially led to the allowance of additions of 2% $CaCl_2 \cdot H_2O$ by weight of cement to concrete to accelerate set. More recent work, together with the release of bound chloride as concrete ages, has led to a recognition that maximum allowable chlorides in concrete should be a function of both the nature of the steel and the expected service environment of the concrete. The recommendations of American Concrete Institute Committee 201, which are being revised at this time, are given in Table 2.

Table 2 Recommended maximum water-soluble chloride levels in concrete mix (prior to service) for different reinforced concrete exposures

Type of exposure	Maximum recommended chloride level, wt% of concrete
Prestressed concrete	0.06
Conventionally reinforced concrete in a moist environment and exposed to chloride	0.10
Conventionally reinforced concrete in a moist environment but not exposed to chloride (includes locations where the concrete will be occasionally wetted, such as parking garages, waterfront structures, and areas with potential moisturecondensation)	0.15
Aboveground building construction where the concrete will stay dry	No limit

A compounding factor in the chloride-induced corrosion of reinforcement is the action of macrocells. Because of the electrically continuous and extensive nature of the typical reinforcement in concrete, differences in chloride concentration and oxygen level at different locations on the steel can be anticipated. Under these conditions, separated anodic (high-chloride, low-oxygen) and cathodic (low-chloride, high-oxygen) areas can easily develop along the reinforcement, particularly where chloride enters the concrete from an exterior surface. This separate, macrocell action frequently leads to severe corrosion at the anodic areas. Macrocell action has been worsened unintentionally during concrete repair. Therefore, the replacement of deteriorated, spalled, chloride-contaminated concrete adjacent to reinforcing steel with fresh, chloride-free concrete can introduce a potent cathode into the system, with the result being accelerated corrosion of the surrounding reinforcement. This can lead to the well-known spall around a spall deterioration phenomenon.

The effect of corrosion induced by such a mechanism is somewhat dependent on the nature of the steel. For reinforcing steel, the major problem arising from an increased corrosion rate is the production of a voluminous oxide, which occupies a greater volume than the steel from which it was produced. Under these circumstances, significant tensile stresses can be introduced into the surrounding cementitious material, leading to cracking of the brittle cementitious material. Calculation of the Pilling-Bedworth ratio (see the article "Gaseous Corrosion Mechanisms" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*) allows the magnitude of the volume expansion to be assessed, but this is typically found to be a factor of between 2 and 10, depending on the exact nature of the corrosion product.

The effect on high-strength prestressing steel may not be the same. Such steel typically has an ultimate tensile strength exceeding 1380 MPa (200 ksi) that is produced by cold forming. As discussed previously, steels of this hardness may be susceptible to stress-corrosion cracking or, more probably, hydrogen embrittlement. In this context, then, corrosion processes that may produce hydrogen can be very deleterious to the structure containing the posttensioning or prestressing. This is due to the possibility of hydrogen embrittlement leading to brittle fracture of this steel and therefore to the loss of compression of the surrounding concrete. Examples of this problem will be discussed later in this article.

Protection Methods

Atmospheric Corrosion. One of the most important aspects of corrosion protection is corrosion prevention through the consideration of the fundamental aspects of good design practice. Such considerations include:

- Avoidance of upturned angles, channels, and so on, that can collect moisture
- Avoidance of pockets within welded structures
- Grinding welds flush
- Elimination of crevices that can lead to accelerated corrosion

Examples of details to avoid, as well as more corrosion-resistant details, are shown in Fig. 4. Although some of these discrepancies can be mitigated by other corrosion protection methods, the selection of weathering steels makes adherence to good design and fabrication detailing mandatory.

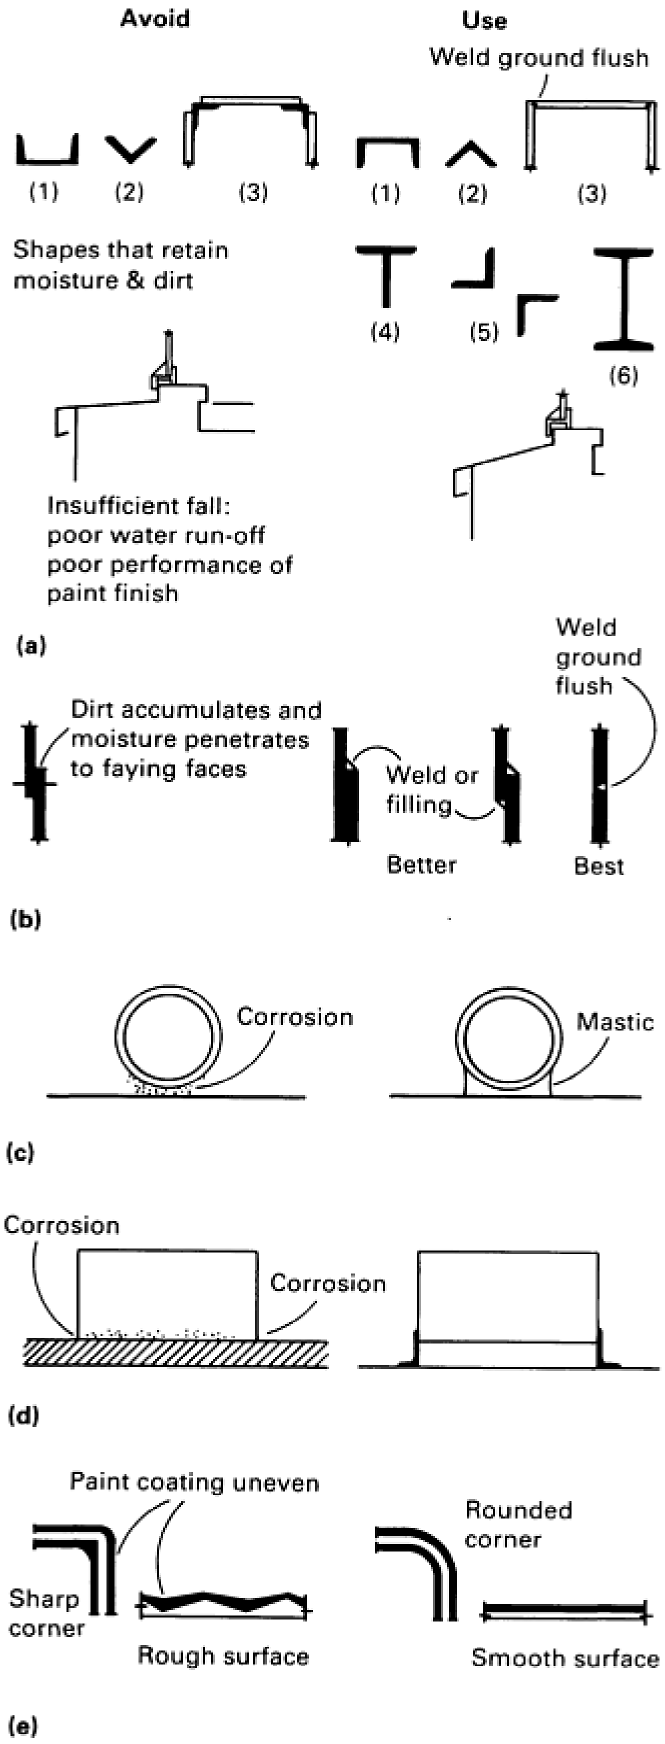

Fig. 4 Design and fabrication details to be considered in corrosion prevention. (a) Constructional members, sills, etc. (b) Joints. (c) Crevices. (d) Air circulation. (e) Corners, edges, and surfaces

Various methods are available for protecting steel against corrosion in so-called atmospheric conditions. The protection system is generally a barrier coating or a metal alloying of the steel that effectively introduces a barrier coating by a normal corrosion process.

The barrier coatings used to protect steel from atmospheric corrosion are of three main types: organic coatings, inorganic coatings, and metallic coatings. The selection of one of these coatings is a function of the expected environmental severity in which the structure is to perform, the corrosivity of that environment, the expected lifetime of the structure, and the possibility of further maintenance coating. In other words, coating selection is a combination of both technical and economic considerations.

Organic coatings are perhaps the most frequently used coatings for protecting steel from atmospheric corrosion. This is true with regard to bulk structural steel. However, such components as fasteners rarely have organic coatings, because of the difficulties related to the fit of fastener systems incorporating such coatings and the poor durability of such coatings under abrasion and tightening conditions. A review of the different types of organic coatings that are available is included in the article "Organic Coatings and Linings" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*. Nevertheless, it is important to highlight in this article certain aspects of coatings procedures that are of vital importance in the longevity of the coating.

Although some coatings have recently become available that are less susceptible to the problems of incomplete surface preparation, it is generally recognized that the quality of the surface preparation is a major factor in the service life of the coating. Perhaps the most extensive evaluation of paint behavior as a function of substrate preparation has been conducted by the Steel Structures Painting Council, which has issued a series of standards on different degrees of cleaning prior to the application of paints.

The degree of cleanliness to be attained depends on the sensitivity of the chosen paint system to the level of surface cleanliness and on the required longevity of the system. In this regard, it is important to recognize that different methods of surface preparation are available, including centrifugal blast cleaning, abrasive air-blast cleaning, water-blast cleaning, and hand and power tool cleaning. Hand tool and power tool cleaning are typically employed only where small areas must be cleaned of preexisting scale and paint. It is also important to recognize that contaminants on steel surfaces that are not visible to the naked eye may influence the longevity of the subsequent coating. Therefore, inorganic salts present on the surface may dissolve in water that permeates through the coating, leading to significant corrosion of the substrate. Standard blast-cleaning techniques typically do not remove such contaminants, but water-blast cleaning does. However, this again becomes a matter of economics and the sensitivity of the coating system to such surface contamination.

The selection of a coating system is influenced by consideration of the likely corrosive environment and the consequences of coating failure. Figure 5 shows some typical preparation and coating formulations. Therefore, the need for increased durability of the coating increases with the corrosivity of the environment. In this regard, much steel is enclosed within building walls, and such steel is frequently only lightly shop primed. Indeed, it has been questioned whether such coating is in fact necessary, based on the environment in which the steel is to perform.

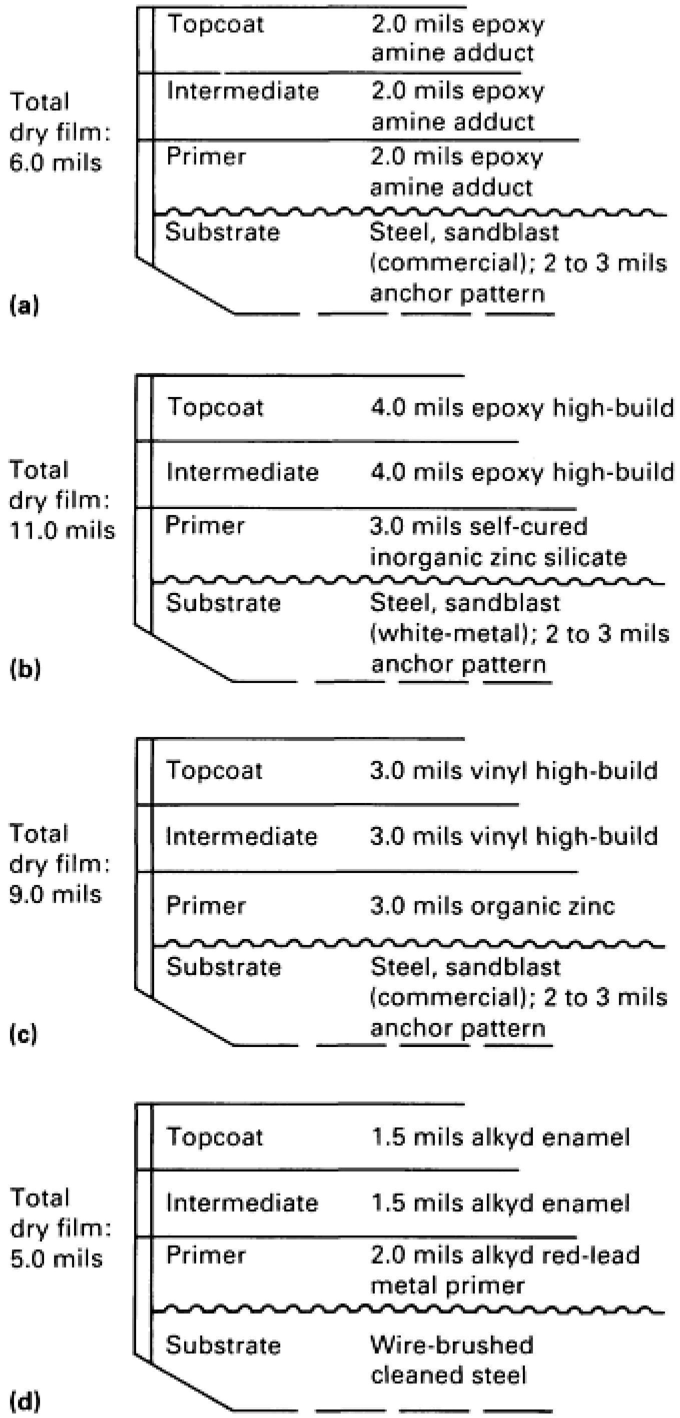

Fig. 5 Typical coating systems used in various environments. (a) Adduct-cured epoxy for use in exposure to solvent spillage and alkaline dust. (b) Inorganic zinc-epoxy used for severe marine exposures. (c) Inorganic zinc/vinyl coating system for use in mild industrial environments. (d) Alkyd-base coating for mild inland atmospheric exposure. Source: Ref 5

One of the problems in making decisions of this type is that the severity of the environment may not be adequately documented. Therefore, if there is exfiltration from the building, then condensation of the steel members can occur, resulting in an extended time of wetness and a corrosion rate that is significantly greater than might otherwise be anticipated. Under these circumstances, the thin shop primer may be much less than adequate, and a more rigorous corrosion prevention system should be considered. Adverse effects on such steel may include the pick-up of corrosive constituents (particularly chloride) from other building materials--for example, from mortar during passage of water through masonry walls. If flashing systems are inadequate, then such water may reach structural steel and cause

significant corrosion damage. This is another factor that needs to be considered whenever the so-called benign environment within, for example, the walls of a building is considered.

Inorganic Coatings. Other forms of coating that are midway between the use of a metallic coating and an organic coating are the inorganic zinc-rich coatings. The ultimate life expectancy of this type of material in severe weathering service has not yet been established, but over 20 years of experience has shown that complete protection of the steel substrate is still being provided. Protection in this case is largely the result of the good corrosion resistance of zinc itself. Indeed, it has been pointed out that the cured inorganic zinc-silicate films can be thought of as a cross between hot-dip galvanizing and a fused ceramic. Because of the absence of organics, inorganic coatings are considered to have the best solvent resistance of any type of protective coating. This makes them very useful for structures in which vapors are present, such as chemical plants, petroleum refineries, and production facilities.

The metallic coating system most commonly used for steel in structures is zinc coating. These coatings can be applied by hot-dip galvanizing or by electroplating for smaller components, such as bolts. Electroplating generally lays down a considerably thinner zinc layer than hot-dip galvanizing. Therefore, the service life of this layer can be considered to be shorter. The results of numerous investigations of the service lives of galvanized coatings show that the life of the coating is a function of the coating thickness and the environment in which it will operate. This is illustrated schematically in Fig. 6. Therefore, the thickness of galvanizing to be placed on a piece of structural steel will depend on an assessment of the nature of the environment and the required longevity. In this regard, the severity of the environment within a cavity wall where a zinc coating material may frequently be used has recently become a significant concern; this issue will be discussed later in this article. Additional information on zinc coatings is available in the articles "Continuous Hot Dip Coatings" and "Batch Process Hot Dip Galvanizing" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook* and "Corrosion of Zinc" in this Volume.

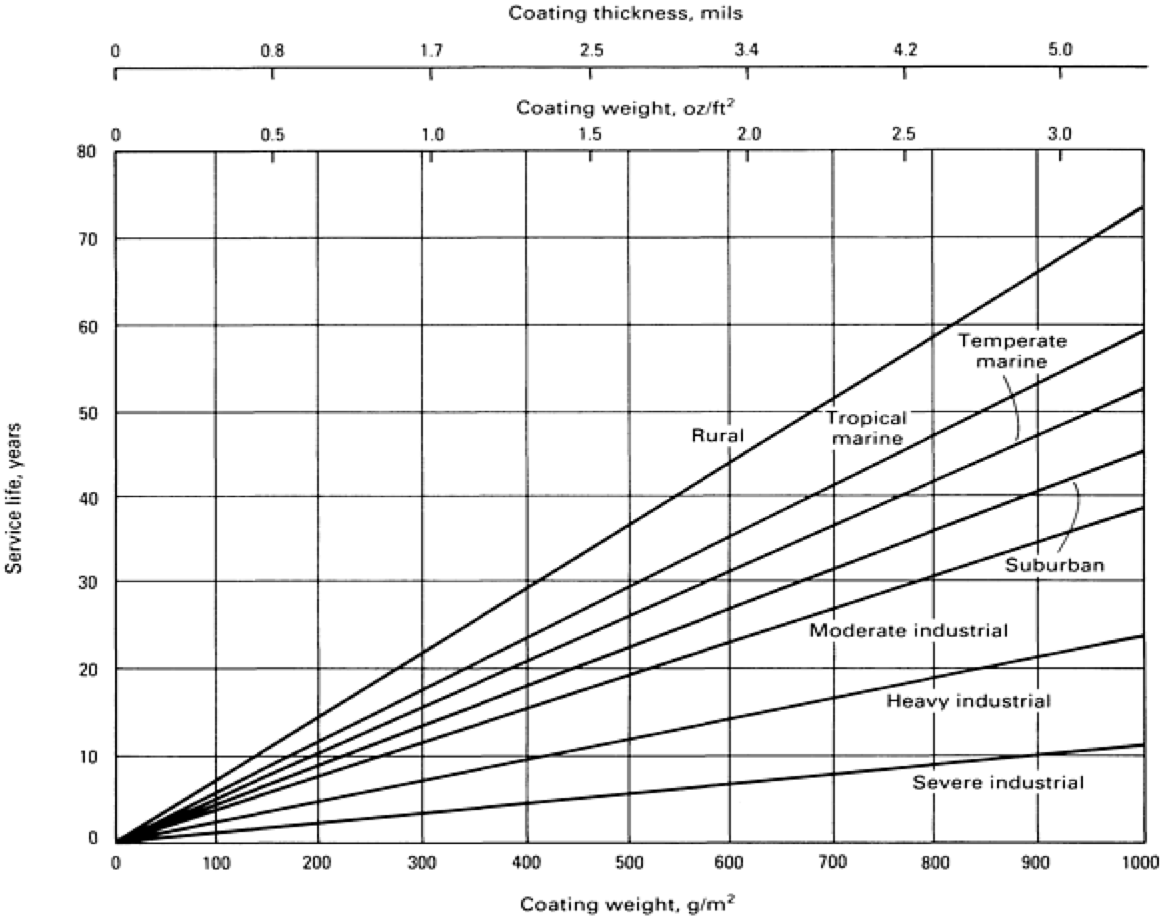

Fig. 6 Effect of zinc coating weight on service life of galvanized steel sheet in various environments. Service life is measured in years to the first appearance of significant rusting.

For small components, other protective systems are available. These include cadmium plating, which is considered to be more corrosion-resistant than zinc in marine environments, Cadmium plating is currently viewed with caution because of the toxicity of the plating solutions and the difficulty of disposal. Nevertheless, the general corrosion resistance of cadmium plate makes the process worthy of consideration where the small steel components used in structures must be protected.

Weathering Steels. The final method of protection against atmospheric corrosion is the use of weathering steels. In this class of materials (typified by ASTM specifications A 588 for buildings and A 709 for bridges), small amounts of alloying elements--typically nickel, chromium, and copper--are added to the steel (Ref 6, 7). Under certain fairly specific situations, these alloying elements are incorporated into the oxide layer that forms on the steel, leading to the formation of a dense, more protective oxide. This oxide then serves as a barrier to further penetration of moisture and effectively acts almost as a "self-painted" coating, lessening the need for any other coating protection. An example of the improvement in corrosion behavior of such steels in an industrial environment is shown in Fig. 7.

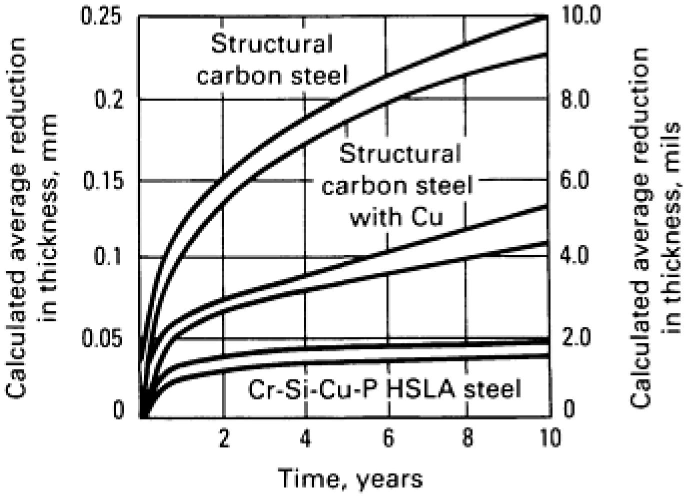

Fig. 7 Corrosion of three types of steels in an industrial atmosphere. Shaded areas indicate range for individual specimens

Although such behavior is valuable, it must be recognized that it will be observed only under certain circumstances. Interestingly, the improvement is generally best in an industrially polluted environment; less improvement is noted in environments containing chloride--for example, marine environments. Also, the film or patina must undergo repeated wetting and drying to develop. Any use of this type of steel in a structure in which this type of exposure is not available will not allow development of the protection. In this context, it is vital to adhere to good corrosion-resistant design techniques when using weathering steels to ensure that the steel performs adequately. Any design or fabrication detail that incorporates crevices, improperly bolted connections, and so on, will lead to behavior in which weathering steels exhibit no advantage over other steels. Examples of problems related to the use of weathering steels will be discussed later in this article.

The ultimate situation in using alloying elements to promote a barrier layer on the surface of steel involves the introduction of sufficient chromium into the steel to allow the formation of stable chromic oxide. The stainless steels contain a minimum of 12% Cr and are highly resistant to normal atmospheric conditions. More highly alloyed steels may be required for resistance to severe marine environments. However, the high cost of these materials precludes their use except in critical situations. Such critical situations may, for example, arise in connection bolts, ties, and other components that must perform for the expected service life of the building and are usually not located where inspection, maintenance, or replacement can be easily carried out. Under these circumstances the use of stainless steel becomes a highly advantageous proposition.

Cementitious Systems. As discussed previously in this article, cementitious systems normally provide a protective environment to steel. Indeed, the longevity of reinforced steel structures supports this situation. The major factors that cause steel embedded in cementitious systems to corrode and lead to significant problems are the influences of carbonation and chloride infiltration. Under both of these circumstances, the normally protective oxide film on steel

breaks down, and corrosion will proceed at a rate that is sufficient to cause loss of cross section, buildup of voluminous corrosion product with resultant spalling of overlying material, or, in specific cases, hydrogen embrittlement.

One of the principal methods of preventing this problem in construction has been to place over the steel a concrete or cementitious material of sufficient quality and thickness to reduce dramatically any infiltration of chlorine or CO_2 to the steel surface. Because of the diffusion-controlled nature of this infiltration, the depth and permeability of the material have a significant effect on the time at which sufficient chloride or CO_2 reaches the steel surface to allow corrosion to initiate and propagate. The obvious first step in preventing such corrosion is to ensure adequate concrete depth (typically taken as 50 mm, or 2 in., of clear cover over reinforcing steel) and to use as low a water-to-cement ratio as feasible to promote impermeability within the concrete.

Although this approach may be considered adequate for reducing carbonation problems within the expected service lives of structures, it may not be sufficient to mitigate chloride-induced corrosion. The reasons are twofold. First, the chloride may have been added to the mix; therefore, it would already be present at the level of the reinforcing steel, irrespective of the type, quality, or depth of concrete cover used. Such problems can be prevented at the specification stage; the use of any chloride-containing admixtures for any purpose whatsoever should be prohibited. Also, research has shown that prestressing steel may be even more deleteriously affected by chloride-induced corrosion than conventional reinforcing steel; limits are currently being considered on the amount of chloride permissible within the concrete from any source. Therefore, chloride-bearing aggregate could have a considerable influence on this situation.

Second, in the case of marine environments, and particularly in the application of deicing salt, it becomes difficult, if not impossible, to ensure that the depth of cover and the concrete quality will protect the steel against chloride-induced corrosion attack over the expected service life of the structure. In this case, alternative measures become appropriate. Such measures involve the application of a barrier coating to the steel or to the cementitious surface or the application of cathodic protection to bare steel, generally at a point in the service life of structure at which corrosion damage has already occurred.

Various coatings for steel in reinforced concrete structures have been evaluated. These can generally be grouped into either organic coatings and inorganic or metallic coatings. Extensive work has demonstrated that the alkaline nature of concrete and the intrusion of chloride into the concrete are best resisted by an epoxy coating on the steel. Moreover, the reinforcing steel must be carefully prepared prior to application of the coating, and the application method is critical--typically, an electrostatic powder spray, followed by baking to fuse the coating. Bars coated in accordance with this technique have been successfully used in bridge decks since 1973. As necessary, repair of such coatings in the field at bar ends and holidays, and so on, can be undertaken using repair materials.

Epoxy coatings have been viewed with some disfavor on the basis of bond strength, that is, the possible tendency of the coating to prevent adequate bond development by lessening adhesion at the deformation/concrete interface. However, it would appear that recommended coating thicknesses, which are typically 0.18 ± 0.05 mm (7 ± 2 mils), mitigate this problem and do not lead to a significant reduction in bond strength.

Additional concerns when using epoxy coatings include the possibility that small holidays in the coating may be subject to accelerated attack, particularly if epoxy-coated steel is used only in the top mat of the structure, and that bare steel is used in, for example, the bottom mat. This is a traditional construction method when deicing salt is applied to the top surface; the bare steel at the bottom is rarely subjected to any chlorine levels, because of the large distance (up to 250 mm, or 10 in.) from the upper surface of the concrete to the level of the lower mat. Although it is not clear that this concern has been completely eliminated, testing has indicated that it may not be a major problem. In any case, such a problem could of course be largely eliminated through the use of epoxy-coated reinforcing steel throughout the entire structure.

Metallic coatings for steel in cementitious materials are typically limited to zinc and nickel. As previously discussed, small items, such as threaded fasteners, can be cadmium plated. Cadmium plate is apparently slightly more resistant to chloride attack in cementitious materials than zinc because of the apparent formation of a basic cadmium chloride. Furthermore, metallic cadmium does not appear to form expansive corrosion products. However, the problems with continued cadmium coating related to environmental concerns have already been addressed.

By far the most common coating for steel in contact with cementitious materials is zinc--either applied by hot-dip galvanizing or plating. The factors that determine the rate and which zinc and zinc-coated steel corrode in cementitious

materials are directly linked to the formation and preservation of protective films. A stable film, and therefore low corrosion rates, occurs on the zinc in the pH range of about 6 to 12.5.

Figure 8 shows the influence of pH on the corrosion rate of zinc. It is interesting that the pH of concrete or mortar in the noncarbonated state is typically about 12.5, which is the minimum on the pH versus corrosion rate curve for zinc. This observation is supported by laboratory studies evaluating the corrosion rate of zinc. Therefore, for a noncarbonated mortar, the corrosion rate of zinc in contact with this mortar is effectively zero. Once carbonation occurs, and the pH falls below 10, then the corrosion rate increases--typically to a level of approximately 0.5 to 0.8 μm/yr (0.02 to 0.03 mil/yr). Therefore the typical use of hot-dip galvanizing as a protective measure for steel exposed to carbonated concrete or, more particularly mortar, is well founded. A typical 64-μm (2.5-mil) galvanized coating would be expected to last over 80 years under these circumstances.

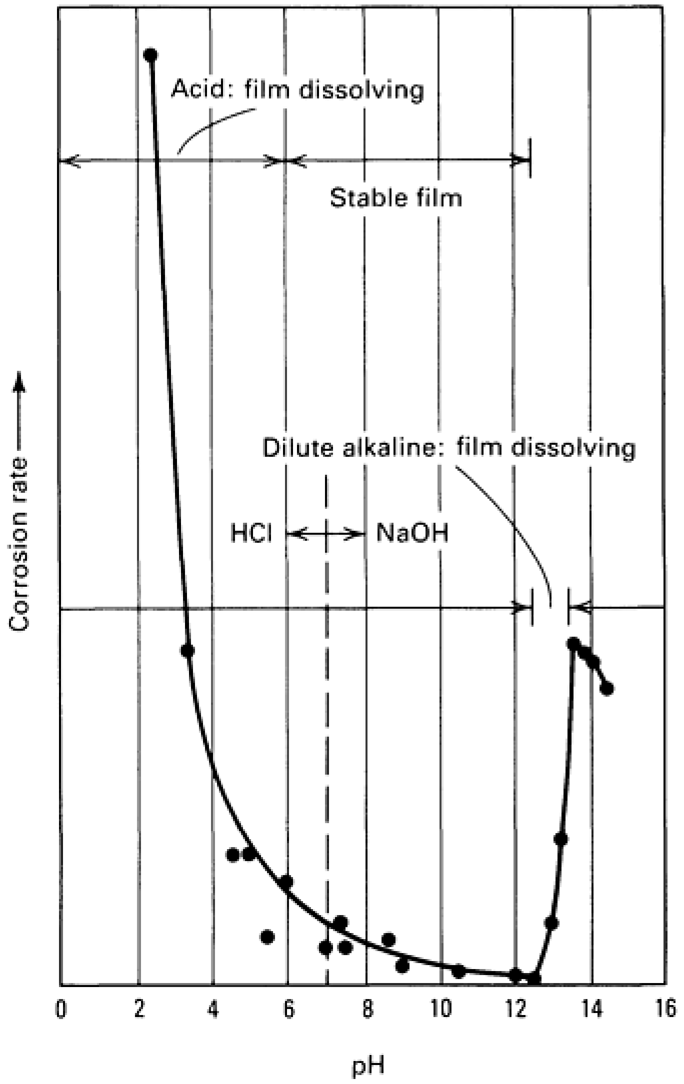

Fig. 8 Corrosion of zinc in aqueous solutions as a function of pH

Zinc does not perform as well when chloride is present in the cementitious material either as a result of the original additions or the infiltration from the exterior. The use of zinc coatings under these circumstances has been the subject of much debate. Indeed, the results of laboratory testing--including experiments related to the use of simulated environments such as $Ca(OH)_2$ solution with and without added quantities of chloride as well as laboratory-prepared specimens of zinc-coated steel in contact with chloride-contaminated concrete--may be in disagreement with studies of large-scale structures that have been fabricated with galvanized steel. Some of these structures are bridge decks; those that are most commonly used to promote galvanized reinforcement are structures in the Caribbean, where no cracking of the structure was noted even after chloride up to a level of approximately 0.26% by weight of the concrete was present at the rebar interface. In this case, however, approximately one-tenth of the original galvanized coating and been removed, and further corrosion could be anticipated. In other locations where galvanized steel has been used in bridge decks, no reports are currently known in the open literature regarding the performance of such steel as compared to bare steel in the same type of environment.

Studies on reinforced concrete specimens containing galvanized steel, exposed to either marine environments or to artificial ponding in NaCl solution, have led to a variety of conclusions related to the effectiveness of the galvanizing. Therefore, this range is all the way from a supposedly accelerated cracking of concrete containing galvanized steel to a retardation of such cracking as compared with bare steel. However, it should be emphasized that in most of these studies cracking of the overlying concrete has occurred, indicating that galvanizing is at best a palliative coating for steel in chloride-contaminated cementitious materials.

As far as is known, there is no direct evidence regarding the ability of galvanized steel to withstand a certain level of chloride before significant corrosion can occur. In studies using electrical resistance probes, it was found that for chloride added to mortar during the mixing phase the corrosion rate of zinc was of the order of 0.5 μm/yr (0.02 mils/yr) for a chloride content of approximately 0.15% by weight of the mortar. However, in the presence of carbonation, this corrosion

rate increased to 10 μm/yr (0.4 mils/yr). Therefore, for a standard galvanized coating approximately 64 μm (2.5 mils) thick, the coating would survive for only 6.5 years under this latter condition. This is notwithstanding possible problems related to the production of nonprotective and expansive corrosion products from the zinc layer.

Zinc hydroxychloride has been found to form during the corrosion of zinc in chloride-contaminated cementitious materials. This component is significantly expansive compared to the zinc from which it was produced and can therefore cause cracking of overlying cementitious materials even before corrosion of substrate steel has occurred.

Therefore, in general, although zinc-coated steel is somewhat more resistant to chloride-induced corrosion than bare steel, the zinc cannot be relied on to provide protection indefinitely. Indeed, the products of corrosion of the zinc itself may lead to cracking of the overlying material.

In addition to applying barrier coatings on the embedded steel to resist corrosion, a similar barrier surface may be applied to the concrete or masonry surface to resist the penetration of constituents contributing to corrosion. These generally take the form of physical barriers, including:

- Organic membranes applied to the concrete surface (often used on parking structures)
- Low-permeability cementitious-base overlays and repairs (incorporating latex)
- Polymer impregnation of the concrete (rarely used)
- Waterproofing agents, for example, drying oils, stearates, or silanes

In using one of these systems, care must be taken not to trap the corrosive environment within the structure. Silanes applied to surfaces are effective in preventing this action; they allow water vapor transmission out of the structure but no liquid penetration into the structure. This prevents oxygen transport to the steel while allowing the structure to dry.

The final method of protection for steel in cementitious materials that may be subject to corrosion is cathodic protection. Cathodic protection is a well-established means of preventing corrosion in a variety of environments, particularly for pipelines buried in soil or immersed in seawater. It has also been successfully used to ensure the protection of steel pipelines that are buried or encased in concrete.

It was first applied to the problem of deterioration of conventionally reinforced concrete structures in California. During early experiments, it was necessary to use a total surface anode over the entire structure to be protected--in this case, the top surface of the bridge deck--because of the low throwing power of the anode and general high electrical resistance of concrete. Using this technique, large decks could be protected with only 10 W of power. The surface anode method did, however, require the embedment of current supply anodes in a relatively soft overlay composed of coke-asphalt mix, which itself could be subject to fairly rapid deterioration by traffic. This technique has been used by others with some success, and it continues to be improved.

One of the more important developments in the cathodic protection of structures is the use of different anode systems that allow horizontal surfaces other than upward facing to be protected. Therefore, the development of anode systems incorporating conductive polymers, conductive paints, and conductive concrete (containing typically coke or graphite) has made possible the cathodic protection of the underside of vertical surfaces of reinforced concrete structures. An example of such an application will be discussed later in this article.

Impressed-current systems using platinized wires in slots in the concrete surface, surrounded by conductive grout, have been used. Experience with this system has been clouded because of the deterioration of the grout and surrounding concrete by the low pH developed at the anode and by the poor throwing power of the anode. Studies have also been conducted on galvanic (sacrificial anode) systems, which are to be distinguished from the impressed-current systems previously discussed. In this type of system, for example, zinc wires are placed in slots above reinforcing steel, and the sacrificial action of the zinc is then transferred to the steel directly below.

Some additional observations can be made with regard to the cathodic protection of reinforced steel in concrete. First, care must be exercised whenever cathodic protection systems are considered for application to high-strength steels, such as those used in posttensioning and prestressing systems. This is because of the previously discussed possible susceptibility of these steels to hydrogen embrittlement, which may result from the overprotection of the steel and subsequent hydrogen evolution at the steel/concrete or mortar interface.

Furthermore, unbonded systems are expected to be difficult to protect because of the possible insulating effects of the sheath that is present around the steel. Indeed, even if such unbonded systems could be protected, the poor throwing power due to the lack of contact between the posttensioning steel and the surrounding concrete is probably an insurmountable problem.

Finally, considerable attention is currently being given to the appropriate criteria for cathodic protection of steel in cementitious materials. Although a transfer of the usual protection criteria from, for example, pipe in soil systems has been made, there is some doubt as to the reasonability or, in some cases, the adequacy of such protection criteria. This is due to the different nature of the environment between concrete and soil, particularly as it relates to pH. Therefore, rather than relying on a -0.85-V copper sulfate electrode as a standard criteria for protection, there is more interest in using a potential shift mechanisms and in using *E*-log *i* plots for establishing the adequacy of the protection. More information on cathodic protection is available in the article "Cathodic Protection" in this Volume.

Case Histories

This section will cite specific examples of failures and problems that have occurred within structures to illustrate the general principles discussed previously, to point out those factors that bear most heavily ont he development of a particular problem or failure, and to determined how protective or preventive measures can be implemented to repair the structure or to prevent the occurrence of failure in the future. The case history data to be discussed have been primarily taken from investigations of buildings or structures conducted by the author. Other examples of failures are available in the literature.

Failures Involving Corrosion of Structural Steel

In general, failures related to the corrosion of conventional structural steel (that which has been painted or otherwise protected) are, in the author's experience, rare. Cases do exist in which excessive humidity or chloride-laden water has contacted the metal. The use of weathering steels, however, has caused significant problems, particularly where the necessary design features and environment have not been carefully considered during selection of the material. Two examples of problems involving weathering steels will be discussed.

Example 1: Weathering Steel Corrosion in a Stadium.

A large sports stadium situated about 300 m (1000 ft) from the ocean was built with weathering steel in the major structural members. The steel was used not only for the exposed portions of the structures but also beneath the stands. Significant corrosion and rust flaking were noted on this steel at several locations:

- Underneath the stands, where air circulation was poor and no standard wetting/drying could be anticipated (Fig. 9)
- At sheltered locations on the exterior, again where standard wetting/drying was not possible (Fig. 10)
- At joint details, where the important concepts of removal of crevices and pockets to retain water had not been practiced in the design of joints for the structure (Fig. 11)

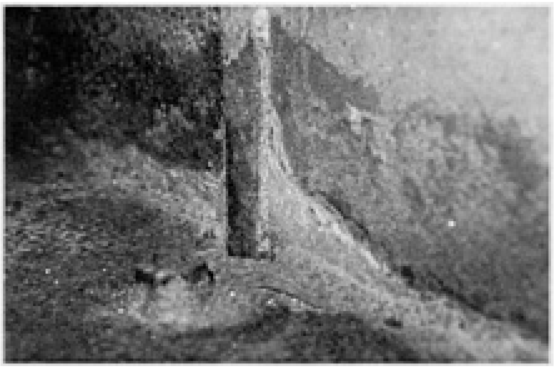

Fig. 9 Heavy buildup of corrosion scale on weathering steel structural members in conditions of poor air

circulation, high humidity, and no wetting/drying

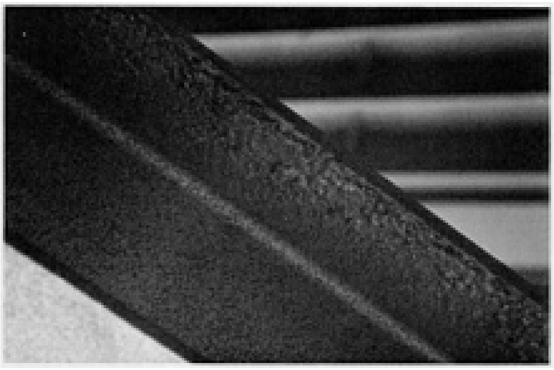

Fig. 10 Corrosion scale buildup on weathering steel structural members, which were in a sheltered area on a building exterior where wetting and drying did not occur

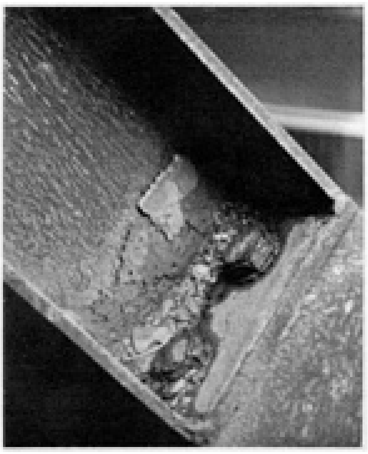

Fig. 11 Heavy corrosion scale buildup on structural members of weathering steel at a pocket where water could collect and stand

The major problem associated with this structure was the amount of corrosion occurring on the structural steel beneath the stands. Although the loads in these structures were determined to be low, it was apparent that corrosion protection would be necessary. A series of tests was conducted to determine the optimum coating protocol, including surface preparation, type of coating, thickness, and number of coats.

This example serves to point out the important factors to be considered by the designer when weathering steel is selected. In particular, the protective patina can be developed adequately only with exposure to weather. Furthermore, marine environments are not conducive to the formation of such a patina, which apparently develops best in an industrial environment with relatively high sulfur levels in the atmosphere.

Example 2: Corrosion of Weathering Steel in a Hotel Parking Garage.

A hotel parking garage in the Northeast was constructed with weathering steel in the columns and beams, along with conventional reinforced concrete slabs placed as the decks. The hotel and garage were situated in an area that experienced considerable amounts of snow and freezing temperatures. Deicing salt was commonly applied to roadways adjacent to the structure and was also probably applied to the reinforced concrete slabs themselves. Severe deterioration was noted in the weathering steel beams and columns, particularly those adjacent to leakage points of water, and in expansion joints. This corrosion was caused by contact with the deicing salt laden water, effectively destroying any patina that may have been expected to develop on the steel and leading to the production of voluminous, nonprotective oxides.

The failure in this case caused by a lack of appreciation of the environment to which the weathering steel was to be exposed. Possible solutions to the problem include the use of coatings on the steel to protect it from further contact with chloride-laden water and the correction of water paths that lead to contact with the deicing salt. The sheltered location of most of the steel, however, would not allow effective patina development. Prohibiting the use of chloride deicing salt on the garage decks would probably reduce the problem somewhat, although pickup of deicing salt from roadways and track-in into the garage is a perpetually deleterious condition that is unavoidable.

Corrosion of Conventional Reinforcement

Corrosion of steel in conventionally reinforced concrete in deicing salt application areas and in marine areas is a well-known phenomenon on such structures as bridge decks and bridge support structures. This corrosion phenomenon has received sufficient illustration in the literature and will not be repeated here. An example of a similar problem that has occurred in a building not subjected to deicing salt or ambient marine environments will be used as an illustrative example.

Example 3: Corrosion of Reinforcing Steel in Building Columns.

Figure 12 shows an example of a supporting column in a dormitory building on a Midwestern campus. The columns are of conventionally reinforced concrete, with a spiral of reinforcement that closely approaches the surface of the concrete column. The concrete showed cracking and spalling within a few years after its installation. Laboratory examination indicated that the concrete cover was low, that the concrete over the steel was carbonated close to the outer surface, and that the concrete contained a significant amount of chloride, apparently added during construction, that was due to either the presence of chloride-bearing aggregate or the deliberate addition of admixtures such as $CaCl_2$. Corrosion of embedded steel was severe in places (Fig. 13).

Fig. 12 Corrosion-induced spalling of overlying concrete on reinforced columns. See also Fig. 13

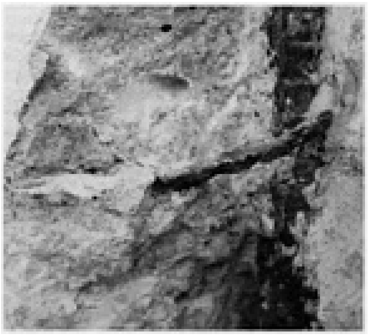

Fig. 13 Severe corrosion on reinforcing steel from the column shown in Fig. 12

Because of the likelihood that carbonation might progress into the concrete and, together with the chloride, affect the more deeply embedded steel, the following repair plan was devised. First, loose and spalled concrete was chipped out of the columns. Second, the columns were shotcreted to a depth of approximately 25 mm (1 in.) above the topmost reinforcement. Finally, an impressed-current cathodic protection system was placed on the columns, using conductive polymer anodes with integral lead wires. This system was positioned above the surface of the concrete with stands, and the entire system was finally covered with an additional layer of concrete. This minimal concrete removal, along with the subsequent buildup and installation of a cathodic protection system, was far more cost effective than the alternatives, which included complete demolition of the column or removal of sufficient overlying concrete cover to necessitate shoring of the column to support the building above.

Corrosion of Ties and Anchors

The corrosion of steel ties and anchors used to attach masonry walls to the building frame, to the backup (usually concrete block) wall, or, more recently, to steel studs has been a source of significant concern. Cases are known in which such ties or anchors have corroded, either in the mortar or in the airspace. Two examples will be given.

Example 4: Corrosion of Nonstandard Wall Ties.

In a hospital in the Midwest, cracking of masonry walls at attachment points to a steel stud backup was observed. When the interior wallboard was removed, the tie between the brick wall and the steel stud was found to be in the form of a light-weight C-channel that had been flattened and bent to form a 90° angle (Fig. 14). The flattened portion of the anchor was inserted into the masonry bed joint and down into the core of the brick. The remaining, intact portion of the channel was attached to the backup steel stud by a self-tapping screw. No effective corrosion protection had been applied to the angles; they exhibited remnants of shop primer at certain locations, but the efficacy of any coating had been destroyed during the bending and flattening process.

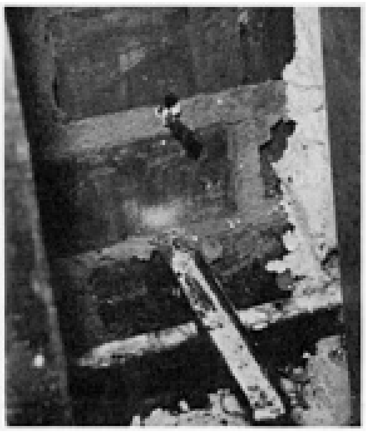

Fig. 14 Unconventional masonry tie constructed from flattened C-channel and bent to enter the brick core

Severe corrosion of these angles had occurred in the airspace adjacent to the brick masonry. This was apparently caused by water running down the interior wall and becoming trapped. Also, the water would become trapped in the crevices formed by the flattened channel.

One effect of this corrosion was the interaction with low cyclic stresses imposed on the tie due to movements between the stud and the wall, leading to cracking of the tie. This was particularly prevalent where corrosion had reduced the tie thickness to a fraction of its original dimension (Fig. 15).

Fig. 15 Severe corrosion and cracking (arrows) on wall tie

This problem could have been prevented through the use of several alternative techniques, including:

- The use of more conventional ties incorporating corrosion-resistant coatings such as galvanizing
- The use of heavy organic coatings after bending to prevent corrosion. If this type of tie was to be mandated, then heavy organic coatings applied after bending would have been appropriate

The solution to this problem could involve the use of alternative supplementary anchors or the dismantling of portions of the wall containing such ties and replacement with masonry containing more appropriate anchors to ensure continued support of the masonry wall.

In addition to the corrosion of steel in the wall cavity itself, which can generally be lessened by the use of galvanizing, there is also concern regarding the corrosion that may occur in the portion of the tie within the mortar. This is the case where significant chloride is present in the mortar, particularly where chloride and carbonation can interest to produce a significantly corrosive environment. In these cases, the commonly used galvanized thicknesses may not be sufficient to protect the steel over the expected service life of the building.

Example 5: Cracking of Masonry Caused by Corrosion of Ties and Anchors.

In many structures that have incorporated high-bond masonry mortar additives, the release of Cl^- due to alkaline hydrolysis has significantly corroded uncoated and coated (zinc and cadmium) steel. This has been the case for laid-in-place buildings (utilizing conventional ties) and for penalized buildings (in which embedment of connection devices in the mortar is used to affix the panels to the building frame). In this situation, connection devices may corrode within the mortar, with subsequent cracking of overlying masonry due to the buildup of corrosion product.

Examples of masonry exhibiting such cracking, which radiates from corroded embedded ties and anchors, are shown in Fig. 16 and 17. Under these circumstances, the integrity of the anchor becomes extremely suspect. No effective method is known for alleviating this problem once it has occurred. Alternative approaches have involved the use of heavily organic coated anchors (for example, epoxy coatings) or the use of austenitic, molybdenum-containing stainless steels, which should resist the onslaught of the Cl^-.

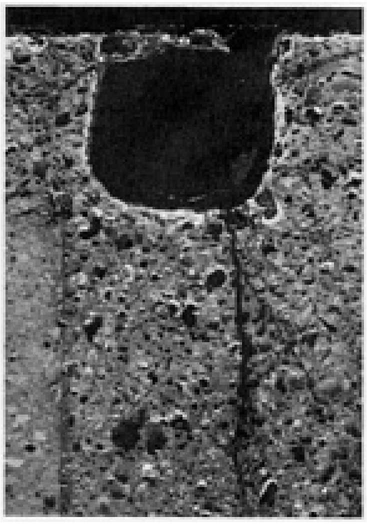

Fig. 16 Corrosion and resulting masonry cracking on anchor embedded in high-bond mortar. See also Fig. 17

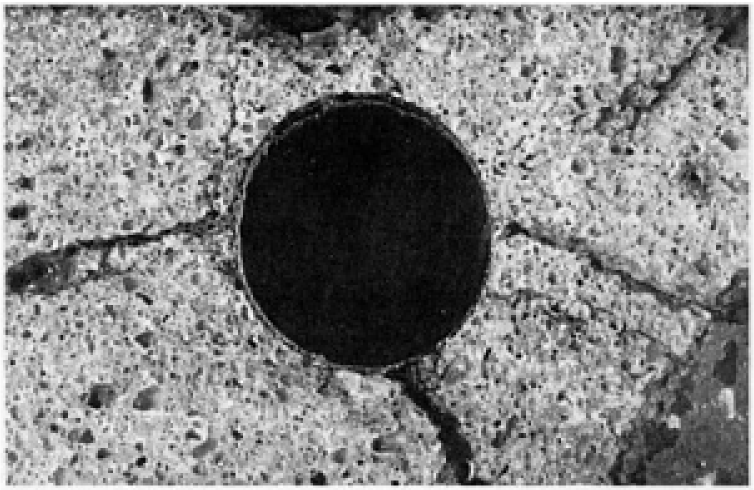

Fig. 17 Corrosion and resulting masonry cracking on an anchor embedded in high-bond mortar. See also Fig. 16

Corrosion of Posttensioning and Prestressing Structures

Unlike other cases of corrosion of steel in structures, the corrosion of posttensioning structures can be troublesome from two viewpoints. First, the possibility exists that substantial corrosion can lead to a loss of cross section and therefore failure of the gripping mechanism for the posttensioning strand or of the posttensioning steel itself. Second, corrosion products on the surface of the material may release sufficient hydrogen to cause hydrogen embrittlement. Two examples will be given.

Example 6: Corrosion of Posttensioning Anchorages.

A posttensioned garage in the snow belt area of the United States exhibited significant corrosion of conventional reinforcement, as noted by the presence of cracking and spalling of overlying concrete. On one occasion, a posttensioning tendon failed. This led to a large-scale investigation of posttensioning members, particularly the anchorages. The anchorages were found to be significantly corroded because of their location adjacent to leaking expansion joints and because they were surrounded by poor, badly consolidated concrete. This had allowed deicing salt to penetrate to the level of the anchorages, leading to some serve corrosion. This was particularly true on the gripping wedges, as illustrated in Fig. 18.

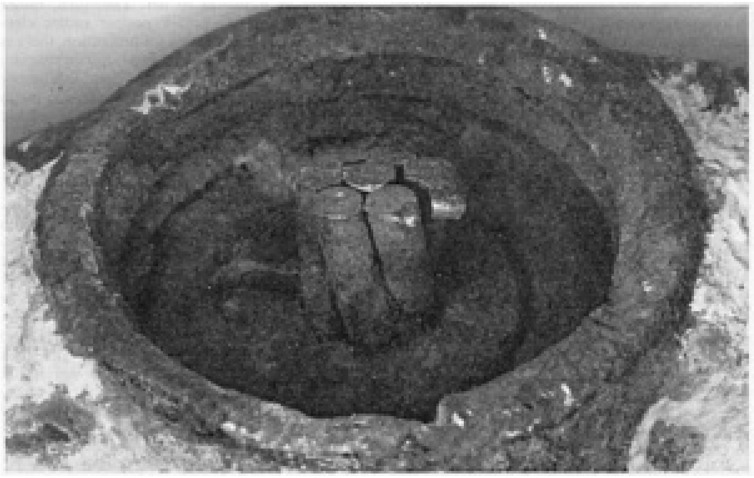

Fig. 18 Corrosion of posttensioning anchorage. Note severe corrosion at the two wedge halves

Several of the anchorages were sufficiently corroded such that alternative anchorages had to be installed. In others, the corrosion was slowed by the injection of water-displacing grease into the anchorage through a grease fitting. This case history shows how poor-quality concrete can significantly affect the performance of metals embedded within it, particularly when the metals are of vital importance to the longevity and safety of the structure.

Example 7: Hydrogen Embrittlement of Posttensioning Wires.

Single 6.4-mm (0.25-in) posttensioning wires failed in a parking garage in the southern portion of the United States. A typical anchorage with a broken buttonhead wire is shown in Fig. 19. Several such wires were removed, and the lengths were examined for signs of corrosion. Localized shallow pitting was common, as illustrated in Fig. 20. Chloride was detected in some of these pits.

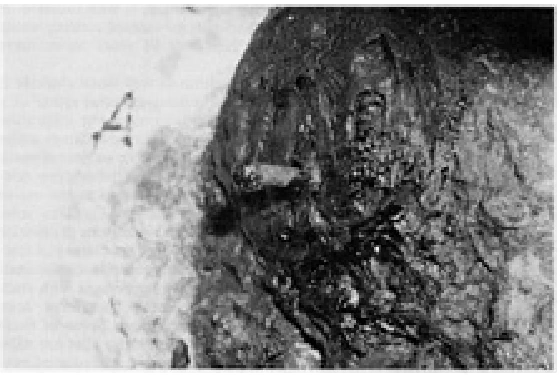

Fig. 19 Posttensioning anchorage with broken wire extending from anchor plate

Fig. 20 Pitting corrosion adjacent to fracture on failed posttensioning wire

Scanning electron microscopy metallography of the ends of the fractures revealed an initial crack that was probably caused by hydrogen embrittlement (Fig. 21). Apparently, this hydrogen embrittlement had occurred because of the presence of the corrosion on the external surface. No chloride was detected on the fracture surface, and none was detected in the overlying concrete. This suggested that the corrosion observed may have initiated before placement of the tendons within the concrete. There is no known method of mitigating this type of problem once it has occurred, although it can be prevented through the use of judicious and careful corrosion-preventive techniques during the storage of the tendons before placement.

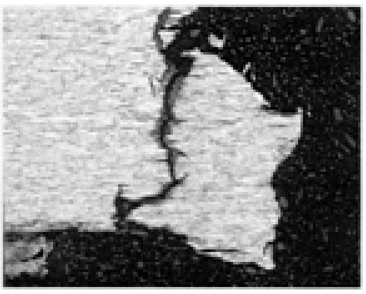

Fig. 21 Metallographic cross section through the fracture initiation region of posttensioning wire. Note secondary cracks. Etched with 2% nital. 55×

Corrosion of Metal Processing Equipment

Introduction

METAL-PROCESSING EQUIPMENT is exposed to numerous corrosive environments and corrosion mechanisms. Heat-treating equipment is subject to high-temperature oxidation, carburization, and sulfidation. Corrosion by molten salts and molten metals is also of concern for heat-treating furnaces and accessories (see the section "Corrosion of Heat-Treating Furnace Accessories" in this article). Equipment for plating, pickling, and anodizing is exposed to acid and alkali solutions at temperatures up to or higher than 100 °C (212 °F) (see the section "Corrosion of Plating, Anodizing, and Pickling Equipment" in this article). Information on materials for and prevention of corrosion in these applications is also available in Volumes 4 and 5 of *ASM Handbook.*

Corrosion of Heat-Treating Furnace Accessories

G.Y. Lai and C.R. Patriarca, Haynes International, Inc.

Heat-treating furnace accessories include a wide variety of components, such as trays, baskets, pots, blowers, thermowells, belts, hangers, bellows, and dampers. Typical heat treatments include annealing, normalizing, hardening, carburizing, nitriding, carbonitriding, brazing, galvanizing, and sintering.

The medium or environment used for heat treating varies from process to process. The high-temperature corrosion of furnace components depends heavily on the environment (or atmosphere) involved in the operation. Typical environments are air, combustion atmospheres, carburizing and nitriding atmospheres, molten salts, and protective atmospheres (such as endothermic atmospheres, nitrogen, argon, hydrogen, and vacuum). Protective atmospheres are used to prevent metallic parts to be heat treated from forming heavy oxide scales during heat treatment. The environment can often be contaminated by impurities, which can greatly accelerate corrosion. These contaminants (such as sulfur, vanadium, and sodium) generally come from fuels used for combustion, from fluxes used for specific operations, and from drawing compounds, lubricants, and other substances that are left on the parts to be heat treated.

The modes of high-temperature corrosion that are most frequently responsible for the degradation of furnace accessories are oxidation, carburization, sulfidation, molten-salt corrosion, and molten-metal corrosion. Each mode of corrosion, along with the corrosion behavior of important engineering alloys, will be discussed in detail in this section. The compositions of the alloys under discussion are given in Table 1.

Oxidation

Oxidation is probably the predominant mode of high-temperature corrosion encountered in the heat-treating industry. The oxidation discussed in this section involves air or combustion atmospheres with little or no contaminants, such as sulfur, chlorine, alkali metals, and salt.

Carbon steel and alloy steels generally have adequate oxidation resistance for reasonable service lives for furnace accessories at temperatures to 540 °C (1000 °F) (Ref 1). At intermediate temperatures of 540 to 870 °C (1000 to 1600 °F) heat-resistant stainless steels, such as AISI types 304, 316, 309, and 446, generally exhibit good oxidation resistance (Ref 1). Very few oxidation data have been reported in this temperature range. As the temperature increases above 870 °C (1600 °F), many stainless steels begin to suffer rapid oxidation. Better heat-resistant materials, such as the nickel-base high-performance alloys, are needed for furnace components in order to combat oxidation at these high temperatures.

Numerous oxidation tests on commercial alloys have been performed at 980 °C (1800 °F) or higher. For example, in one investigation, cyclic oxidation tests were conducted in air, with each cycle consisting of exposing the samples at 980 °C (1800 °F) for 15 min, followed by a 5-min air cooling (Ref 2). The performance ranking, in order of decreasing performance, was found to be as follows: Inconel alloy 600, Incoloy alloy 800, type 310 stainless steel, type 309 stainless steel, type 347 stainless steel, and type 304 stainless steel. Similar cyclic oxidation tests performed in air at 1150, 1205, and 1260 °C (2100, 2200, and 2300 °F), cycling to room temperature by air cooling after every 50 h at temperature, showed Inconel alloy 601 to be the best performer, followed by Inconel alloy 600 and Incoloy alloy 800 (Ref 3).

In another study, ferritic stainless steels such as E-Brite and type 446 were shown to be significantly better than type 310 and Incoloy alloy 800H in terms of cyclic oxidation resistance in air (Ref 4). These test results showed weight change data of 2.2 mg/cm^2 for E-Brite, 10.0 mg/cm^2 for type 446 stainless steel, -83.2 mg/cm^2 for alloy 800, and -90.3 mg/cm^2 for type 310 stainless steel after exposure of the samples for a total of 1000 h with 15 min at 980 °C (1800 °F) and 5 min at room temperature. A separate test was also conducted. This test involved exposure of the samples at 980 °C (1800 °F) for 1000 h in air with interruptions after 1, 20, 40, 60, 80, 100, 220, 364, and 512 h for cooling to room temperature. The weight change results of these four alloys were -12.9, 9.2, 1.7, and 3.0 mg/cm^2 for E-Brite, type 446 stainless steel, type 310 stainless steel, and alloy 800, respectively (Ref 4).

An oxidation data base for a wide variety of commercial alloys, including stainless steels, iron-nickel-chromium alloys, nickel-chromium-iron alloys, and high-performance alloys, was recently generated (Ref 5). Tests were conducted in air at 980, 1095, 1150, and 1205 °C (1800, 2000, 2100, and 2200 °F) for 1008 h. The samples were cooled to room temperature once a week (each 168 h) for visual inspection. The results are summarized in Table 2.

Table 2 Results of 1008-h cyclic oxidation test in flowing air at temperatures indicated

Specimens were cycled to room temperature once a week.

(a) Average metal affected = metal loss + internal penetration.

(b) All figures shown as greater than stated value represent extrapolation of tests in which samples were consumed in less than 1008 h.

Type 304 stainless steel and type 316 stainless steel both exhibited severe oxidation attack at 980 °C (1800 °F), while type 446 showed relatively mild attack. Many higher alloys, such as Incoloy alloy 800 and the nickel- and cobalt-base alloys, showed little attack. At 1095 °C (2000 °F), type 446 stainless steel suffered severe oxidation. Iron-nickel-chromium alloys, such as Incoloy alloy 800H and RA330, also suffered significant oxidation. Many nickel-base alloys, however, still exhibited little oxidation. At 1150 °C (2100 °F), most alloys suffered unacceptable oxidation, with the exception of only a few nickel-base alloys. At 1205 °C (2200 °F), all alloys except Haynes alloy 214 suffered severe attack. Alloy 214 showed negligible oxidation at all the test temperatures. This alloy is different from all of the other alloys tested in that it forms an aluminum oxide (Al_2O_3) scale when heated to elevated temperatures. Other alloys tested form chromium oxide (Cr_2O_3) scales when heated to elevated temperatures.

The alloy performance rankings (Ref 6) generated from the field in the furnace atmosphere produced by the combustion of natural gas were found to correspond closely to the air oxidation data presented in Table 2. The alumina-forming alloy 214 was found to be the best performer (Ref 6).

Carburization

Materials problems due to carburization are quite common in heat-treating components associated with carburizing furnaces. The environment in the carburizing furnace typically has a carbon activity that is significantly higher than that

in the alloy of the furnace component. Therefore, carbon is transferred from the environment to the alloy. This results in the carburization of the alloy, and the carburized alloy becomes embrittled.

Nickel-base alloys are generally considered to be more resistant to carburization than stainless steels. The results of 25-h carburization tests performed at 1095 °C (2000 °F) in a gas mixture consisting of 2% methane (CH_4) and 98% hydrogen revealed the weight gain data of 2.78, 5.33, 18.35, and 18.91 mg/cm^2 for Inconel alloy 600, Incoloy alloy 800, type 310 stainless steel and type 309 stainless steel, respectively (Ref 7). Extensive carburization tests were recently performed to investigate 22 commercial alloys, including stainless steels, iron-chromium-nickel alloys, nickel-chromium-iron alloys, and nickel- and cobalt-base alloys (Ref 8). Tests were performed for 215 h at 870 and 925 °C (1600 and 1700 °F) and for 55 h at 980 °C (1800 °F) in a gas mixture consisting of 5 vol% hydrogen, 5 vol% CH_4, 5 vol% carbon monoxide (CO), and the balance argon. The results failed to reveal any correlation between carburization resistance and the alloy base. Nevertheless, it was found that the alumina-forming Haynes alloy 214 was the most resistant to carburization among all of the alloys tested.

These findings were confirmed in 24-h tests performed at 1095 °C (2000 °F) in the same gas mixture. The carburization data are summarized in Table 3. In this study, alloy 214 (an alumina former) was found to be significantly better than the chromia formers tested. Among the chromia formers, however, there is some question regarding the significance of the differences within the carbon absorption range of 9.9 to 14.4 mg/cm^2. Perhaps less severe environments are required to separate the capabilities of these alloys. Field testing will be an excellent way of determining alloy performance ranking. However, few data are available. Field tests were recently conducted in a heat-treating furnace used for carburizing, carbonitriding, and neutral hardening operations (Ref 9). Both RA333 and Inconel alloy 601 were found to exhibit better carburization resistance than any of the alloys tested, which included RA330, Incoloy alloy 800, and alloy DS.

Table 3 Results of 24-h carburization tests performed at 1095 °C (2000 °F) in Ar-5H_2-5CO-5CH_4

Incoloy alloy 800H	12.6
RA330	12.7
Haynes alloy 25	14.4

Metal dusting is another frequently encountered mode of corrosion that is associated with carburizing furnaces. Metal dusting tends to occur in a region where the carbonaceous gas atmosphere becomes stagnant. The alloy normally suffers rapid metal wastage. The corrosion products (or wastage) generally consist of carbon soots, metal, metal carbides, and metal oxides. The attack is normally initiated from the metal surface that is in contact with the furnace refractory. The furnace components that suffer metal dusting include thermowells, probes, and anchors. Figure 1 illustrates the metal dusting attack on Multimet alloy. The component was perforated as a result of metal dusting. Metal dusting problems have also been reported in petro-chemical processing (Ref 10).

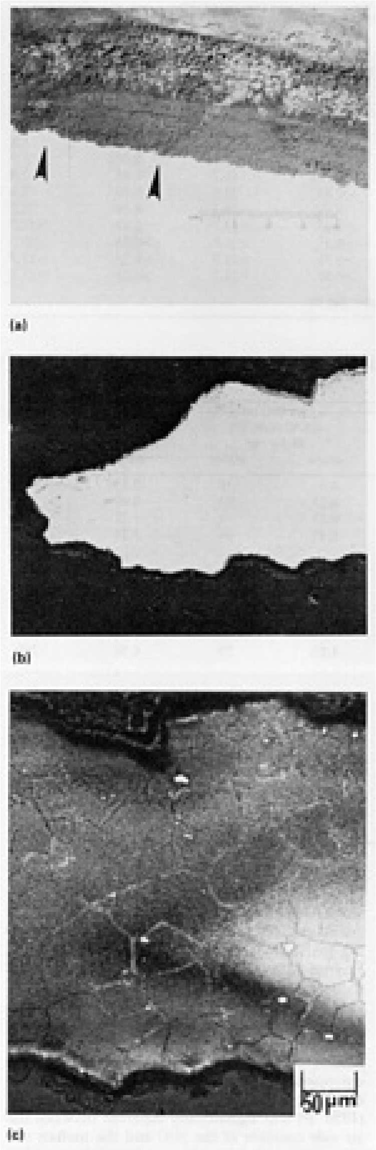

Fig. 1 Metal dusting of a Multimet alloy component at the refractory interface in a carburizing furnace. (a) Perforation of the component (arrows). (b) Cross section of the sample showing severe pitting. (c) Severe carburization beneath the pitted area

Metal dusting has been encountered with straight chromium steels, austenitic stainless steels, and nickel- and cobalt-base alloys. All of these alloys are chromia formers; that is, they form Cr_2O_3 scales when heated to elevated temperatures. No work has been reported on the alloy systems that form a much more stable oxide scale, such as Al_2O_3. The Al_2O_3 scale was found to be much more resistant to carburization attack than the Cr_2O_3 scale (Ref 8). Because metal dusting is a form of carburization, it would appear that alumina formers, such as Haynes alloy 214, would also be more resistant to metal dusting.

Sulfidation

Furnace environments can sometimes be contaminated with sulfur. Sulfur can come from fuels, fluxes used for specific operations, and cutting oil left on the parts to be heat treated, among other sources. Sulfur in the furnace environment could greatly reduce the service lives of components through sulfidation attack.

It is well known that nickel-base alloys are highly susceptible to catastrophic sulfidation due to the formation of nickel-rich sulfides, which melt at about 650 °C (1200 °F). Figure 2 illustrates catastrophic failure of a nickel-chromium-iron alloy tube due to sulfidation attack in a heat-treating furnace. The liquid-appearing nickel-rich sulfide phases are clearly visible.

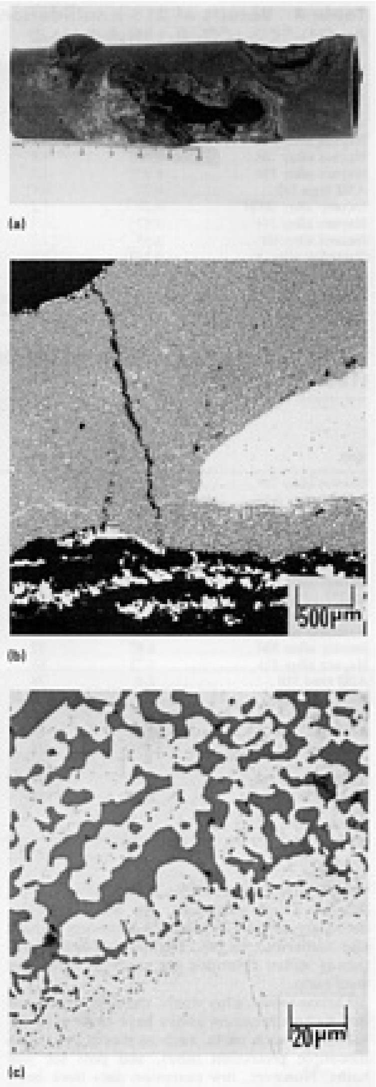

Fig. 2 Catastrophic sulfidation of an Inconel 601 furnace tube. The furnace atmosphere was contaminated with sulfur; the component failed after less than 1 month at 925 °C (1700 °F). (a) General view, (b) Cross section of the perforated area showing liquid-appearing nickel-rich sulfides. (c) Higher-magnification view of nickel-rich sulfides

The sulfidation of metals and alloys has been the subject of numerous investigations. However, the investigations involving commercial alloys examined only a limited number of alloys in each case. This frequently does not provide designers or engineers with a sufficient number of alloys to make an informed materials selection. A comprehensive sulfidation study was recently undertaken to determine the relative alloy rankings of base alloys (Ref 11). Tests were performed at 760, 870, and 980 °C (1400, 1600, and 1800 °F) for 215 h in a gas mixture consisting of 5% hydrogen, 5% CO, 1% carbon dioxide (CO_2), 0.15% hydrogen sulfide (H_2S), 0.1% H_2O, and the balance argon. The cobalt-base alloys were found to be the best performers, followed by iron-base alloys, and then nickel-base alloys, which, as a group, were generally the worst performers. Among iron-base alloys, the iron-nickel-cobalt-chromium alloy 556 was better than iron-nickel-chromium alloys such as Incoloy alloy 800H and type 310 stainless steel. The test results of representative alloys from each alloy base group are summarized in Table 4.

Molten-Salt Corrosion

Molten salts are widely used in the heat-treating industry for tempering, annealing, hardening, reheating, carburizing, and other operations. The salts that are commonly used include nitrates, carbonates, cyanides, chlorides, and caustics, depending on the operation. For example, a mixture of nitrates and nitrites is normally used for tempering and quenching. An alkali chloride-carbonate mixture is used for annealing ferrous and nonferrous metals. Neutral salts baths containing mixed chlorides are used for hardening steel parts.

Carbon steels, alloy steels, stainless steels, and iron-nickel-chromium alloys have been used for various furnace parts, such as electrodes, thermocouple protection tubes, and pots for salt baths. However, few corrosion data have been reported involving heat-treating salts.

One investigation recently provided corrosion data in molten sodium-potassium nitrate ($NaNO_3$-KNO_3) salts. The results of this study are given in Table 5. The nickel-chromium-iron-aluminum-yttrium alloy (alloy 214), nickel-chromium-iron alloys (Inconel alloys 600 and 601), and nickel-chromium-molybdenum alloys (Hastelloy alloys N and S) performed significantly better than stainless steels and iron-nickel-chromium alloys such as Incoloy alloy 800H and RA330. The data generated from 1-month tests in a neutral salt bath containing a mixture of barium, potassium, and sodium chlorides ($BaCl_2$, KCl, and NaCl) at 845 °C (1550 °F) were recently reported (Ref 6). The results are summarized in Table 6. The cobalt-base Haynes alloy 188 was found to be the best performer; the nickel-chromium-iron Inconel alloy 600 was the worst. Somewhat similar results were obtained in laboratory tests conducted for 100h at 845 °C (1550 °F) in NaCl. These data are given in Table 7. Haynes alloy 188 was found to be the best, and Inconel alloy 600 the worst.

In some cases, the salt vapors could cause high-temperature corrosion attack that is significantly worse than that caused by contact with the molten salt. For example, it was found that the corrosion of a nickel-base alloy salt pot containing molten $BaCl_2$-KCl-NaCl mixture at 1010 °C (1850 °F) was significantly different between the air side (outside of the pot)

and the molten salt side (inside) (Ref 14). The outside of the pot (that is, the air side contaminated with salt vapors) suffered three times as much attack as the inside of the pot, which was in contact with molten salt. No corrosion data were reported with respect to this type of accelerated oxidation attack involving molten salt vapors.

Molten-Metal Corrosion

Some heat-treating operations involve molten metals. Lead is used as a heat-treating medium. Cast iron and carbon steels have been used for components in contact with molten lead at temperatures at 480 °C (900 °F). In a 1242-h test in molten lead in an open crucible at 600 °C (1110 °F). Inconel alloy 600 was not appreciably attacked either at or below the liquid-metal surface (Ref 15). At 675 °C (1250 °F) for 1281 h in molten lead, Inconel alloy 600 suffered severe corrosion attack (Ref 15). Few corrosion data in molten lead have been reported in the literature.

The molten-zinc bath is used for galvanizing processes. Few corrosion data are available in the literature to allow engineers to make an informed materials selection for furnace components in contact with molten zinc. Carbon steel is generally used for the furnace components. Iron-nickel-cobalt-chromium alloys such as Haynes alloy 556 also have been reported for use as baskets.

Corrosion of Plating, Anodizing, and Pickling Equipment

Earl C. Groshart, Boeing Aerospace Company

An electroplating, anodizing, or pickling shop environment is highly corrosive to metals. The metals used in the construction of equipment to be employed in this environment must be inert to the environment or must be protected from it.

Tanks

The common materials for constructing tanks for plating, anodizing, and pickling are carbon steel and stainless steel, usually one of the austenitic (18Cr-8Ni) varieties. Concrete, plastic, and fiberglass, either alone or with reinforcing, as well as wood, also are used. Of these, only the metals offer any serious corrosion problems. The nonmetals, however, must be carefully selected to prevent contamination of the processing solutions. Table 8 recommends tank materials for the various solutions found in the finishing shop.

Metal Tank Design to Minimize Corrosion. Tank closure welds should be smooth or should be ground to provide a smooth surface. This not only facilitates the application of liners but also eliminates rough welds (inside the tank or outside) in which solution can be entrapped. Entrapped solution can result in the formation of a corrosion cell. Outside reinforcing should be welded with continuous welds. Tack or intermittent welds should not be used, because they leave open and unprotected overlapping areas in which solutions can be trapped and crevice corrosion can occur. If intermittent welds cannot be avoided, the overlaps should be sealed as shown in Fig. 3. Whenever possible, structural supports should be positioned vertically; again, this is done to help prevent trapping of the solutions. Corrosion occurs around outlets and flanges that are not designed to prevent the solution from contacting the metal. This is also true of overflows built into the tank; if the overflow is deep and/or narrow, it becomes difficult to line and protect it from solutions. The use of O-rings in flanges is a means of keeping the flanges free of solution, but O-rings are expensive and therefore not widely used. More information on designing to prevent or minimize corrosion is available in the article "Designing to Minimize Corrosion" in *Corrosion: Fundamentals, Testing, and Protection,* Volume 13A of *ASM Handbook.*

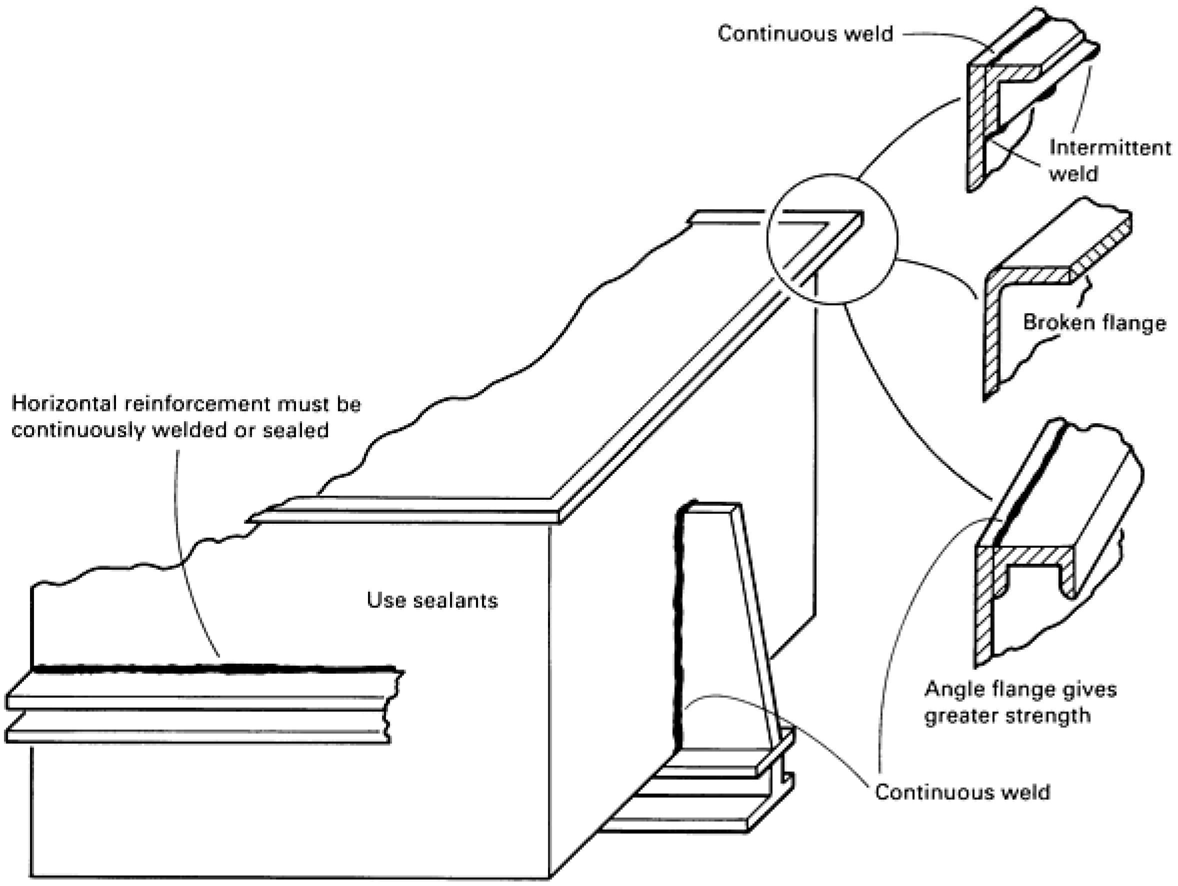

Fig. 3 Tank design details for preventing or minimizing corrosion

Corrosion Protection for Steel Tanks. The outside of a carbon steel tank must be protected, regardless of what is contained in the tank. For example, a steel tank containing an alkaline cleaner will not need protection on the inside, where the alkaline cleaner will keep the steel passivated and at a very low corrosion rate; however, the outside surfaces, which are exposed only to water and the corrosive environment of the shop atmosphere, will corrode severely. Protection of the outside surfaces of corrosion-resistant steel tanks is generally not necessary, except where crevices are possible and oxygen cells can be set up. However, because the tank material is corrosion resistant, overlapping joints are frequently ignored; this provides an initiation site for corrosion.

Protective coating for the outside of a steel tank should include a good two- or three-coat paint system. Epoxies, vinyls, or polyurethanes can be used. A system that consists of an epoxy primer applied over a clean, sandblasted surface, followed by two coats of a two-art urethane topcoat, will provide adequate protection in a finishing shop environment. Vinyl systems are immune to all solutions except very strong solvents and are excellent coatings for tank surfaces. Vinyl systems are also adequate for the inside surfaces of rinse and holding tanks. Vinyls should be applied only to clean,

sandblasted (white metal) surfaces and should be a complete system; that is, primer and topcoat should both come from the same manufacturer and should be matched to each other.

Coal tar and epoxy-modified coal tar systems are excellent tank coatings. This coatings can be used on the inside and outside surfaces of cold tanks, such as rinse tanks. Epoxy-modified coatings tend to soften in contact with hot cleaning, pickling, or plating baths. The epoxy-modified coatings, however, are excellent for tanking understructures, such as the I-beams that keep the tanks off the floor and for the floor itself. All of these coatings can be applied to corrosion-resistant steel tanks, if required. The coal tars and the epoxy-modified coal tars are especially useful as coatings on the bottoms of tanks and between the tank and floor supports, where they are used to prevent crevices in overlapping joints.

The insides of carbon steel tanks used in the metal-finishing industry can also be protected by nonmetal liners. Materials for this application are listed in Table 8. Liners that are applied directly to the steel walls (hot melts, Table 8) should offer sufficient protection for the steel. The drop-in liners--whether thay are made outside of the tank by molding (or other methods) or are made inside of the tank by welding or adhesive bonding--leave the tank wall unprotected and create an ideal crevice corrosion area. Water and solutions will leak between the liner and the tank regardless of how carefully the flanges are made and sealed to the tank. The inside surfaces of these tanks should ideally be protected in the same manner as the outside. However, a heavy coat (or two line coats) of primer on these steel surfaces will offer sufficient protection so that wetting of the inside of the tank does not become an emergency.

Other Plating, Anodizing, and Pickling Equipment

In addition to tanks, other equipment, such as rectifiers, heaters, pumps, racks, bus bars, and wiring, is subject to corrosion in the environment of the finishing shop.

Wiring. In general, installation of electrical wiring is controlled by an electrical code that does not allow bare wires. The wire terminations, however, are subject to corrosion, especially the dc termination. Only copper wire is recommended. Each termination should be made bare and then overcoated with a good grease. Because this will not prevent corrosion of these electrical connections, they should be inspected regularly. When a corrosion product is seen at a joint, the corrosion product should be removed, the joint cleaned and reconnected, and the protective grease replaced. For dc connections to bus bars, a lead or lead-tin coating applied to the terminal lugs, the bar, washers, and bolts offers excellent protection.

Bus Bars. Copper bus bars require constant cleaning not only to remove corrosion products but also to ensure good connections to the rack splines. Tin, lead, and silver coatings on the bars provide temporary protection, but do not eliminate the need for cleaning. The anode bar should be cleaned once or twice a week, and the cathode bar should be cleaned daily.

Racks. A properly designed rack will have bare areas only in the area of the hook, which is required for contact with the bus bar, and in the area of the tip, which is required to make contact with the part. Both of these areas are subject to corrosion from the shop atmosphere during storage and from the solutions during use. These areas require constant maintenance. Aluminum and titanium anodizing racks are subject to anodization of the rack tips. Steel or stainless steel is often used as a rack material for carrying the load of the parts being treated--for example, a heavy crank shaft in a chromium plating bath. Both of these materials require complete masking, even where they make connection with the part. Otherwise, corrosion will not only destroy the rack and weaken the joint but will also contaminate the plating solution. The copper current-carrying member of the rack also requires masking.

Anode splines are generally copper above the plating solution and can be coated with any rack coating, except at the hook where electrical connection is made. Anode splines submerged in the solutions, except those made of the metal that is to dissolve in the bath, must be inert or masked. Rack coatings can be used for this purpose. Inert anodes (that is, those that carry current but do not dissolve), such as titanium in a nickel bath or lead in a chromium bath, are corrosion resistant and require little care. Iron anodes used in an alkaline tin bath, however, are subject to rusting when not in the bath. These units require protection when not in use or require cleaning before use.

Pumps. Conventional metal pumps will corrode in acid solutions. The current trend is to make pumps out of plastic (especially pumps that will be used for small tanks). The body of the pump is usually a grade of phenolic, and the impellers are hard rubber. in this case, the only metal part exposed to the solution is the impeller shaft, which can be fabricated from stainless steel or one of the acid-resistant nickel or cobalt alloys. Metal pumps require constant care to prevent or minimize corrosion.

Heaters. Hot water or steam tank heaters should be treated as part of the boiler system in order to prevent corrosion from the inside. Iron can be used in alkaline solutions, copper can be used in water and neutral solutions, and stainless steel can be used in mildly acid solutions. Stabilized lead can be used in chromic and fluoboric acid solutions. Carbon and ceramic heat exchangers can be used in all solutions except those containing fluoborates and fluorides. The same is true of immersion ceramic or quartz heaters if the framework is coated.

Corrosion in Batteries and Fuel-Cell Power Sources

The ASM Committee on Corrosion of Electrochemical Power Sources; Chairman: Wendy R. Cieslak, Exploratory Batteries Division, Sandia National Laboratories*

Introduction

BATTERIES AND FUEL CELLS, as electrochemical power sources, provide energy through controlled redox reactions. Because these devices contain electrochemically active components, they place metals in contact with environments in which the metals may corrode. The shelf lives of batteries, particularly those that operate at ambient temperatures depend on very slow rates of corrosion of the electrode materials at open circuit. The means of reducing this corrosion must also be evaluated for its influence on performance.

A second major corrosion consideration in electrochemical power sources involves the hardware. Again, shelf lives and service lives depend on very good corrosion resistance of the containment materials and inactive components, such as separators. In those systems in which electrolyte purity is important, even small amounts of corrosion that have not lessened structural integrity can degrade performance.

There is a wide variety of batteries and fuel cells, and new systems are constantly under development (Ref 1, 2, 3, 4, 5). Therefore, to illustrate the types of corrosion phenomena that occur, this article will discuss the following systems: lead-acid batteries, alkaline batteries (in terms of the sintered nickel electrode only), lithium ambient-temperature batteries, aluminum/air batteries, sodium/sulfur batteries, phosphoric acid (H_3PO_4) fuel cells, and molten carbonate fuel cells.

Preparation of the lithium battery review performed at Sandia National Laboratories was supported by the United States Department of Energy under Contract No. DE-ACO4-76DP00789. Preparation of the sodium/sulfur review was supported by the United States Department of Energy, Office of Energy Storages, under Contract No. W-31-109-Eng-38. Funding for the preparation of the fuel cell review was provided by the Assistant Secretary for Fossil Energy, Office of Coal Utilization, Advanced Conversion and Energy Systems Division of the United States Department of Energy under Contract No. DE-ACO3-76SF00098. Philip N. Ross, Jr. acknowledges valuable input from Dave Shores, Charles Baumgartner, and John Appleby.

Lead-Acid Batteries

The principal use of lead in its primary and recycled states is in the manufacture of lead-acid storage batteries. A lead-acid battery consists of groups of positive and negative plates immersed in a concentrated electrolyte solution of sulfuric acid (H_2SO_4) (Ref 6, 7, 8, 9, 10). In its operating form, positive plates contain a web of lead alloy grids coated with lead dioxide (PbO_2). Negative plates contain a web of lead alloy grids coated with pure lead, usually known as sponge lead because of its porous nature. The following reactions occur during charging, and the reverse of these occur upon discharge:

$$\text{Positive: } PbSO_4 + 2H_2O \rightleftharpoons PbO_2 + 3H^+ + HSO_4^- + 2e^- \quad \textbf{(Eq 1)}$$

$$\text{Negative: } PbSO_4 + H^+ + 2e^- \rightleftharpoons Pb + HSO_4^- \quad \textbf{(Eq 2)}$$

During initial charging (first time), on the positive grid, a lead sulfate/lead oxide paste and a very small amount of the lead of the grid surface are converted to PbO_2; consequently, good bonding is obtained between the paste and the grid. On the negative grid, the paste is merely converted to a pure lead sponge. The major corrosion problem in a lead-acid battery occurs during subsequent cyclic discharging and recharging. Overcharging can lead to further conversion of lead to PbO_2 on the positive grid, according to the reaction:

$$Pb + 2O^{2-} \rightleftharpoons PbO_2 + 4e^- \quad \textbf{(Eq 3)}$$

In general, the rate of this process is higher at lower acid concentrations (for example, 2.17 *N*, or 1.065 specific gravity) than at higher concentrations (Ref 11). It is necessary to design the grids such that corrosion of the positive grid is uniform rather than intergranular. Grid corrosion is discussed in Ref 12, 13, 14, 15, 16, 17, 18, 19.

Extremely fine grain sizes (3 to 5 μm) promote a uniform corrosion morphology (Ref 12). However, corrosion mechanisms in wrought and cast grids may differ considerably. For fine-grain cast grids, the equiaxed microstructure is susceptible to corrosion creep, or grid growth, in which a combination of corrosion products buildup and mechanical creep shorts the positive and negative grids (Ref 13, 14). Control of wrought alloy microstructures to produce thin, elongated grains can yield superior performance, because the small grain thickness (1 to 2 μm) provides intergranular corrosion resistance and the large grain length (1 to 2 mm, or 0.04 to 0.08 in.) in the grid growth direction provides creep resistance.

Various alloys are used to make grids, including pure lead, lead-antimony alloys with antimony levels from 0.5 to 6%, and, more recently, lead-calcium alloys (Ref 15). Pure lead has limited application as a grid material because it is extremely soft and is prone to severe corrosion creep. However, to take advantage of the good corrosion resistance of the pure metal (better than the commonly used alloys), batteries for certain standby power applications have been designed to allow for creep.

Antimony increases the strength of lead. However, because antimony decreases the hydrogen overvoltage of lead, the battery starts gassing (hydrogen evolution on the negative grid) at normal charging voltages, leading to loss of water from the electrolyte. To reduce this water loss, the trend has been to lower the content of antimony in the grids to 1% or less. With decreased antimony, the alloy becomes softer and the grain size increases, resulting in lower strength and more severe intergranular corrosion. Grain refiners, such as tellurium, are being tried in the industry to combat the intergranular corrosion problem. Nonetheless, modern designs are moving away from antimony alloys, because recent work suggests that even batteries with the low-antimony alloys exhibit up to six times greater water loss than batteries with wrought lead-calcium-tin grids (Ref 16).

Lead-calcium alloys, like pure lead, have extremely high hydrogen overvoltages, a desirable feature for batteries. Most of the automotive industry currently uses batteries with lead-calcium grids, known as maintenance-free batteries, because water loss and corrosion creep problems are minimized for these grids. In general, calcium increases the corrosion rate of lead, especially when the calcium content exceeds 0.075%. Aluminum additions of 50 to 200 ppm help reduce intergranular corrosion by promoting a uniform distribution of hardening precipitates, rather than the grain-boundary precipitation that occurs in aluminum-free lead-calcium alloys (Ref 17). Lead-calcium-tin alloys that have been developed to improve battery performance offer even better resistance to corrosion and grid growth.

Each grid is coated with a paste of lead oxide (PbO), lead sulfate ($PbSO_4$), water, H_2SO_4, binder, and other materials that affect the performance and life objectives of this complex mixture in its final state. If the sulfate content of the paste mixture is higher, the initial grid corrosion rate is lower because of the effect of sulfate on the acid concentration during charging. If the paste layer is thicker, the corrosion rate is higher because the concentration of acid at the grid/paste interface is lower. Battery manufacturers would prefer to use a low acid concentration for the initial fill because low specific gravity acid is more conductive and the batteries are easier to charge. However, as mentioned above, low specific gravity (low concentration) acids are more corrosive. Thus, a balance is established, depending on paste composition, paste layer thickness, and grid alloy corrosion resistance. Lower sulfate levels, thicker paste layers, and grids with lower corrosion resistance need a higher concentration of acid to lessen the chances of grid corrosion.

Trace impurities in the acid, paste, and grids exert considerable influence on grid corrosion. Elements such as copper, nickel, selenium, tellurium, and chromium strongly reduce the hydrogen overvoltage of the battery and thus cause gassing. Gas bubbles that nucleate at the paste/ grid interface cause the paste pellets to break loose, thus increasing corrosion rates by exposing a fresh lead surface (causing another problem since the loose pellets can fall to the bottom of the cell, accumulate, and eventually short electrodes). Iron has a similar effect, but to a lesser extent. Elements such as phosphorus and zinc slow corrosion rates by changing the morphologies and structures of corrosion products, but they also adversely affect battery performance.

Two more factors influence grid corrosion by affecting the acid concentration. The first is the acid-to-material ratio, defined as the theoretical number of ampere-hours required to dissociate the H_2SO_4 completely divided by the theoretical number of ampere-hours generated when all PbO_2 for positive plates is converted to $PbSO_4$. A higher ratio indicates a higher reserve of acid and therefore a smaller chance of corrosion due to low specific gravity acid. The second is acid stratification, a severe problem in stationary batteries. Constant vibration in automotive batteries and motive power batteries keeps the acid mixed. In stationary batteries, however, the acid stratifies with time, and the low specific gravity acid in the upper part of the battery is more corrosive.

Lastly, corrosion and the associated corrosion creep increase with temperature. For example, batteries in Florida, Arizona, or southern California, fail earlier because of grid corrosion than batteries in colder climates. The warmer climates also allow the grid alloys to soften because of overaging, further worsening the creep problem. Also, the trend in automotive design has been toward higher underhood temperatures in order to increase fuel economy and engine efficiency. If this trend continues, the battery may have to be moved to a cooler region of the vehicle.

Temperature must also be monitored during initial charging because the heat generated increases the temperature of the battery. Conventional practice involves charging the battery in steps, with some delay in between each step to reduce the temperature of the battery and minimize corrosion during initial charging.

A fine-grain (<3 μm) grid alloy microstructure, superior grid alloy mechanical properties (ultimate tensile strength: >45 MPa, or 6500 psi, at room temperature), and the absence of detrimental trace elements normally translate into satisfactory corrosion behavior in a properly designed battery. Maintenance-free batteries in passenger cars typically last from 3 to 7 years. Nonetheless, corrosion resistance of lead-acid battery grids is one of the attractive areas of research for increasing the life of the batteries. The development of aluminum-containing lead-calcium-tin alloys has already made it easier to

manufacture high-quality maintenance-free long-lasting lead-acid batteries. With further improvements, the life of the lead-acid battery may double within the next decade.

Sintered Nickel Electrode in Alkaline Batteries

The $Ni(OH)_2/NiOOH$ electrode is used in several rechargeable alkaline battery systems, such as nickel-iron, nickel-zinc, nickel-cadmium, nickel-hydrogen, and nickel-metal hydride. Numerous variations of this electrode exist as a result of the differing requirements of the various battery systems and the optimization of each system for specific applications. Several battery systems and nickel electrode variations are discussed in Ref 2 and 20. This section will discuss the corrosion of a typical sintered electrode.

The electrode consists of a porous nickel matrix that holds the active materials. The matrix is made by sintering nickel powder onto a substrate, such as a nickel-plated perforated steel strip. The electrochemical reaction during charging of the electrode is represented by:

$$Ni(OH)_2 + OH^- \rightleftharpoons NiOOH + H_2O + e^- \qquad \textbf{(Eq 4)}$$

Upon discharge of the electrode, the reverse reaction occurs. During overcharge, the following electrochemical reaction occurs at the electrode:

$$4OH^- \rightleftharpoons 2H_2O + O_2 + 4e^- \qquad \textbf{(Eq 5)}$$

The nickel in the sintered matrix may corrode if sufficient continuous anodic polarization is present under an unfavorable set of conditions, such as elevated temperature, high concentration of alkali hydroxide electrolyte, or high carbonate impurity levels. Such corrosion can be represented by the following:

$$2Ni + O_2 + 2H_2O \rightleftharpoons 2Ni(OH)_2 \qquad \textbf{(Eq 6)}$$

Equation 6 shows that nickel, oxygen, and water are consumed to produce nickel hydroxide ($Ni(OH)_2$). Consumption of water increases the electrolyte concentration to produce a condition even more favorable for corrosion. Excessive corrosion results in loss of electrical continuity between the active material surface and the current collection terminal. However, practical battery systems may cease useful operation long before loss of continuity occurs. Cessation may be associated with corrosion phenomena or may be related to independent causes.

For example, in sealed nickel-cadmium cells designed with a minimum amount of electrolyte, the system may cease operation in the following ways:

- Consumption of the nickel metal matrix due to the production of $Ni(OH)_2$, resulting in an overload of that structure. This weakening of the matrix can lead to excessive swelling and subsequent shorting
- Loss of electrolyte fluidity, or dry out, resulting directly from the consumption of water by the corrosion reaction (Eq 6)
- Loss of electrolyte fluidity due to the production of $Ni(OH)_2$ and consumption of oxygen by the corrosion reaction (Eq 6). This case is different from the one immediately above, as described below

At the negative electrode, while charging a ventable, sealed nickel-cadmium cell, the favored reaction is the reduction of cadmium hydroxide ($Cd(OH)_2$) to cadmium:

$$Cd(OH)_2 + 2e^- \rightleftharpoons Cd + 2OH^- \qquad \textbf{(Eq 7)}$$

Under normal conditions of overcharge, the preferred reaction at the negative electrode is instead the reverse of Eq 5. As previously noted, the preferred reaction at the positive electrode during continuous overcharge is described by Eq 5. This reaction cannot begin, however, until all of the available $Ni(OH)_2$ is oxidized, including the additional amount produced

by the corrosion reaction (Eq 6). Because no oxygen is available until after this additional amount of $Ni(OH)_2$ is oxidized, the preferred reaction at the negative electrode is Eq 7, provided a sufficient amount of uncharged $Cd(OH)_2$ is present in the negative electrode. Furthermore, the amount of oxygen consumed by corrosion reaction (Eq 6) is not available for the reduction reaction represented by the reverse of Eq 5. This condition again favors Eq 7. Sufficient corrosion leads to charging all of the available uncharged $Cd(OH)_2$. When this occurs, the negative electrode will evolve hydrogen instead of reducing oxygen, as described by the following reaction:

$$2H_2O + 2e^- \rightleftharpoons H_2 + 2OH^- \qquad \textbf{(Eq 8)}$$

The net effect of Eq 8 leads to excessive internal gas pressures, causing the gases from the electrolysis of water to be lost from the system through a resealable vent.

The extent to which these corrosion phenomena influence the useful life of a battery system cannot generally be quantified because of the variety of sintered nickel electrodes, battery system designs, and applications. However, tailoring the sintered nickel electrode design and the battery system design to the specific application permits minimization of the corrosion reactions and extends the useful life of the battery.

Lithium Ambient-Temperature Batteries (LAMBs)

Lithium batteries, primarily by virtue of their very high energy density, are being increasingly used for military and commercial applications. Lithium ambient-temperature batteries may be either of the solid cathode (for example, Li/CuO, Li/V_2O_5, $Li/Bi_2Pb_2O_5$, Li/MnO_2, and Li/CF_x) or liquid cathode type (for example, Li/SO_2 and $Li/SOCl_2$) (Ref 21). A corrosion process common to all these systems, although particularly severe for the liquid cathode types, is the formation of a protective passive layer on the lithium anode (Ref 22, 23). Reference 22 reviews the properties of the lithium anode film, which enables the lithium, although thermodynamically unstable, to resist corrosion in nonaqueous electrolytes. However, because the film is also responsible for temporary voltage depressions on load (commonly known as voltage delay), optimization of both storage life and operating response depends on the properties of this layer. These properties are very sensitive to electrolyte composition and impurities, and this is an area of active research (Ref 22, 23, 24, 25, 26, 27). Corrosion of cell hardware by the electrolyte is also a concern, and the literature includes references to corrosion problems in the Li/SO_2 (Ref 28, 29, 30, 31, 32, 33, 34, 35, 36), $Li/SOCl_2$ and other oxyhalides (Ref 37, 38, 39, 40, 41), Li/V_2O_5 (Ref 42, 43, 44), and Li/I_2 (Ref 45) systems, as discussed below.

Lithium/Sulfuric Dioxide (Li/SO_2) Batteries. The electrolyte in Li/SO_2 batteries contains LiBr as the electrolyte salt and SO_2 as the cathode reactant dissolved in acetonitrile, sometimes mixed with propylene carbonate (Ref 21, 28, 29). Hardware corrosion problems in Li/SO_2 cells include glass corrosion, tantalum corrosion in welded regions, corrosion of lithium in contact with nickel, and stress-corrosion cracking (SCC) of the battery can. Figure 1 shows each of these sites on a simplified battery schematic. Glass corrosion is primarily the result of attack by lithium metal to produce lithium oxide (Li_2O) (Ref 28, 30, 31):

$$4Li + SiO_2 \rightleftharpoons 2Li_2O + Si \qquad \textbf{(Eq 9)}$$

The corrosion product Li_2O further corrodes the glass:

$$Li_2O + SiO_2 \rightleftharpoons Li_2SiO_3 \qquad \textbf{(Eq 10)}$$

$$2Li_2O + SiO_2 \rightleftharpoons Li_2SiO_4 \qquad \textbf{(Eq 11)}$$

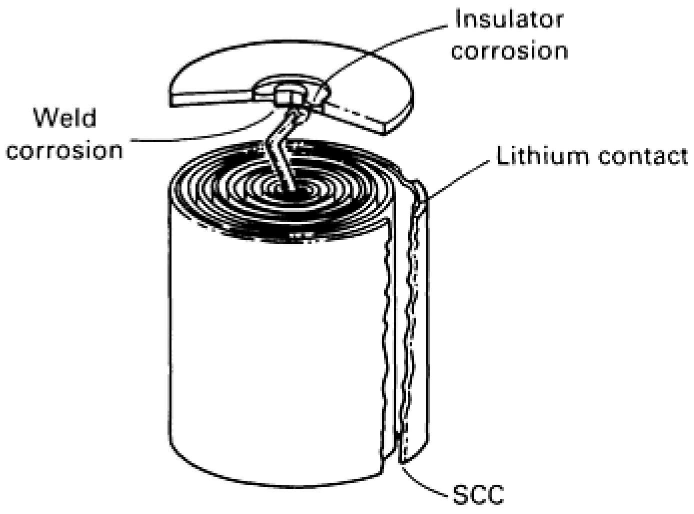

Fig. 1 Sites of corrosion in Li/SO_2 batteries. Courtesy of S.C. Levy

The conductive reaction products contain both lithium metal and oxide and progress across the glass from the negatively charged header to the center pin. Failure occurs either by the conductive product bridging the battery terminals or by thinning of the glass until the stress is sufficient to crack it. Low-silica glasses are more resistant to lithium metal corrosion, and a low-silica glass (TA-23) has been developed that offers satisfactory corrosion resistance (5 years predicted life) (Ref 32). This corrosion resistance has been further improved by at least a factor of ten in new nonsilicate glasses (Ref 33). The mechanism of glass corrosion is common to all lithium cells in which a liquid electrolyte containing lithium ions (Li^+) wets the glass, and the phenomenon has been noted in Li/V_2O_5, Li/$SOCl_2$, and other systems (Ref 29).

Corrosion of tantalum in Li/SO_2 cells has caused failure of the internal contact of the aluminum cathode tab to the tantalum foil strip, which was connected to a tantalum center pin (Ref 28, 30, 31). Both the strip and the pin exhibited intergranular corrosion, with the worst attack occurring in the weld heat-affected zone (HAZ). It was suggested that corrosion was caused by bromine, which was produced by electrolyte decomposition during storage. This problem was solved by changing to a molybdenum pin, which does not appear to be susceptible to corrosion in the battery electrolyte. Furthermore, the weak link--the foil between the aluminum tab and the pin--was removed.

Corrosion of lithium in contact with nickel was manifested by open circuiting of lithium anodes at the point of contact with either the nickel anode strip or the nickel-plated steel can (Ref 28, 30). A study of galvanic corrosion of lithium in the battery electrolyte showed that nickel generated the least galvanic corrosion of the possible contact materials. Therefore, the material was not changed, but the geometry was altered by embedding a nickel grid in the lithium electrode so that contact was made throughout the anode rather than at a single point.

Stress-corrosion cracking of Li/SO_2 battery cans was first observed in nickel-plated low-carbon steel cans (Ref 28, 34, 35). Failures at the pressure relief vents and along the rim of the base were traced to intergranular SCC initiating on the inside surfaces. Cells at 70 °C (160 °F) failed in this manner in less than 2 months. The problem was alleviated by redesigning the base radius to lower the stresses, by proper annealing after forming, and by altering the microstructure to produce elongated grains, which cause SCC to follow a less favorable path.

Proper design to reduce stresses is also important for stainless steel cans, because AISI type 316 stainless steel has been shown to be susceptible to SCC in the Li/SO_2 electrolyte (Ref 36). Stress-corrosion cracking probably also contributed to the fracture of welds attaching headers to battery cans. Mixing of the nickel plating with the carbon steel cans in the weld fusion zone resulted in solidification to austenite, with subsequent transformation to martensite. Stress-corrosion cracking followed the prior-austenite grain boundaries. The weld was redesigned to lower the stresses and correct a weld solidification cracking problem, which should help alleviate SCC.

Lithium/Oxyhalide Cells. The electrolytes in lithium/oxyhalide ($SOCl_2$, SO_2Cl_2, and $POCl_3$) cells are very corrosive to organic materials. Elastomers are unstable, and Teflon is one of the only plastics that is compatible with these electrolytes, although it does react with lithium (Ref 37, 38). Separators are often made of borosilicate glasses, although

these materials also react with lithium. Cell hardware must be made of metals that do not form acidic halides of electronically conductive salt films (Ref 38). Nickel and stainless steels have been shown to resist corrosion in solutions of $SOCl_2$ and SO_2Cl_2, while copper, tin, iron, steel, zinc, magnesium, aluminum, and titanium corrode actively (Ref 37). However, the resistant metals corrode rapidly upon contact with humidity after exposure to oxyhalide electrolytes. The mechanism of corrosion protection of type 316L stainless steel and nickel in 1.5 *M* $LiAlCl_4/SOCl_2$ electrolyte is the *in situ* formation of a protective metal chloride film (Ref 39, 40). Other metals, including platinum, tantalum, molybdenum, and tungsten, appear to be inert to $SOCl_2$ (Ref 40, 41). The passive and the inert metals can both be used in the construction of neutral electrolyte $Li/SOCl_2$ batteries.

The passive metals may be susceptible to environmental cracking in oxyhalide electrolytes. Postmortem analyses of nickel strips that were part of the anode circuit internal to $Li/SOCl_2$ batteries have revealed intergranular failures. Slow strain rate testing of nickel coupled to lithium in the battery electrolyte has demonstrated that intergranular environmental cracking can occur; however, the severity and possible mechanisms have not yet been reported. The phenomenon does not appear to be a practical problem unless the nickel strip is made very small in cross section (quantitative data are not available).

Lithium / Vanadium Pentoxide (Li/V_2O_5) Cells. Corrosion of the type 304 or 316 stainless steel positive grid was the primary cause of failures in Li/V_2O_5 batteries in the early 1970s (Ref 42, 43). The corrosion was thought to be caused by products of the reactions between water and the V_2O_5 or the $LiAsF_6$ + $LiBF_4$/methyl formate electrolyte. However, corrosion severity was found to be directly related to chloride contamination (Ref 42). Chloride levels are currently maintained at less than 100 ppm to avoid corrosion failures. Although certain inhibitors for chloride corrosion, particularly nitrate, looked promising, none was found to work under all conditions (Ref 44).

Lithium / iodine (Li/I_2) batteries, unlike the other lithium batteries discussed, are entirely solid-state. Potential corrosion of the stainless steel cans for Li/I_2 batteries was investigated when a new design placed the iodine-polyvinylpyridine (PVP) depolarizer material in contact with the type 304L stainless steel cans (Ref 45). No significant corrosion occurred in the absence of moisture; however, cells that were fabricated in a more humid environment than usual (1.5% relative humidity versus 0.5%) experienced fine pitting corrosion. The corrosive was suggested to be hydro iodic acid (formed by) reaction of water with iodine), and because the corrosion was self-limiting, the acid was thought to be consumed in the corrosion reaction.

The corrosion problems in LAMBs (with the exception of glass corrosion) tend to be specific to each particular system and, as such, must be considered individually for each system. In general, alternate materials or designs have alleviated the problems, enabling the development of batteries capable of long (at least 5 to 15 years) shelf lives.

Aluminum / Air Batteries

Aluminum/air batteries have been proposed as an alternative energy source for transportation (Ref 46). The cell consists of an air cathode, an aluminum anode, and an electrolyte. The cathodic reduction of the oxygen in air occurs at a metal or carbon electrode of various designs. The electrolytes used include aqueous neutral chloride solutions and alkaline solutions, such as sodium hydroxide and potassium hydroxide (Ref 46). Parasitic corrosion of the aluminum anode is the major corrosion problem in this system.

Parasitic corrosion can be inhibited by alloying additions to the aluminum (Ref 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56) and/or anion additions to the electrolyte (Ref 46, 51, 57). Alloy additions have various effects. Alloying elements that increase corrosion resistance include indium, thallium, phosphorus (Ref 46), and zinc (Ref 53), manganese and iron (Ref 55). Alloying elements that decrease corrosion resistance include copper (Ref 53), gallium and mercury (Ref 46). Magnesium has little effect on the corrosion resistance of aluminum (Ref 55). Because multialloy systems are more practical than binary alloys from a refining standpoint, investigation of multiaddition alloys are more relevant to the future commercialization of these battery systems (Ref 49, 50, 52, 53, 55, 56).

The inhibition of corrosion by the addition of anions to neutral and alkaline electrolytes has also been investigated. Anions that decrease corrosion rates include phosphate (PO_4^{3-}), chromate (CrO_4^{2-}), molybdate (MoO_4^{2-}) (Ref 51), tartrate ($C_4H_4O_6^{2-}$, and borate (BO_3^{3-}) (Ref 57). Anions that exacerbate corrosion include nitrite (NO_2^-), permanganate (MnO_4^-), and silicate (SiO_3^{2-}) (Ref 51). However, in most cases, the influence of these variables on battery performance has not been well documented.

Sodium / Sulfur Batteries

The sodium/sulfur battery, a high-temperature system that operates between 325 and 350 °C (615 and 660 °F), is still under development. The individual cells feature a liquid sodium negative electrode and a liquid positive electrode of sulfur in the charged state or sodium polysulfides in the discharged state. Solid β"-alumina (Al_2O_3), usually in the form of a tube, or conductive glass fibers are used as the electrolyte. In tubular-cell designs (Fig. 2), either the sodium or the sulfur electrode can be on the inside of the tube. In either design, the major materials problem is with the positive current collector; sulfur and sodium polysulfides at 350 °C (660 °F) are extremely corrosive. With the central-sodium cells, the positive current collector is also the cell container so that, in addition to being corrosion resistant and a good electronic conductor, the positive current collector material must also be inexpensive, lightweight, and easy to fabricate into a sealed can. An excellent description of the sodium/sulfur cell and a review of the materials problems are provided in Ref 59.

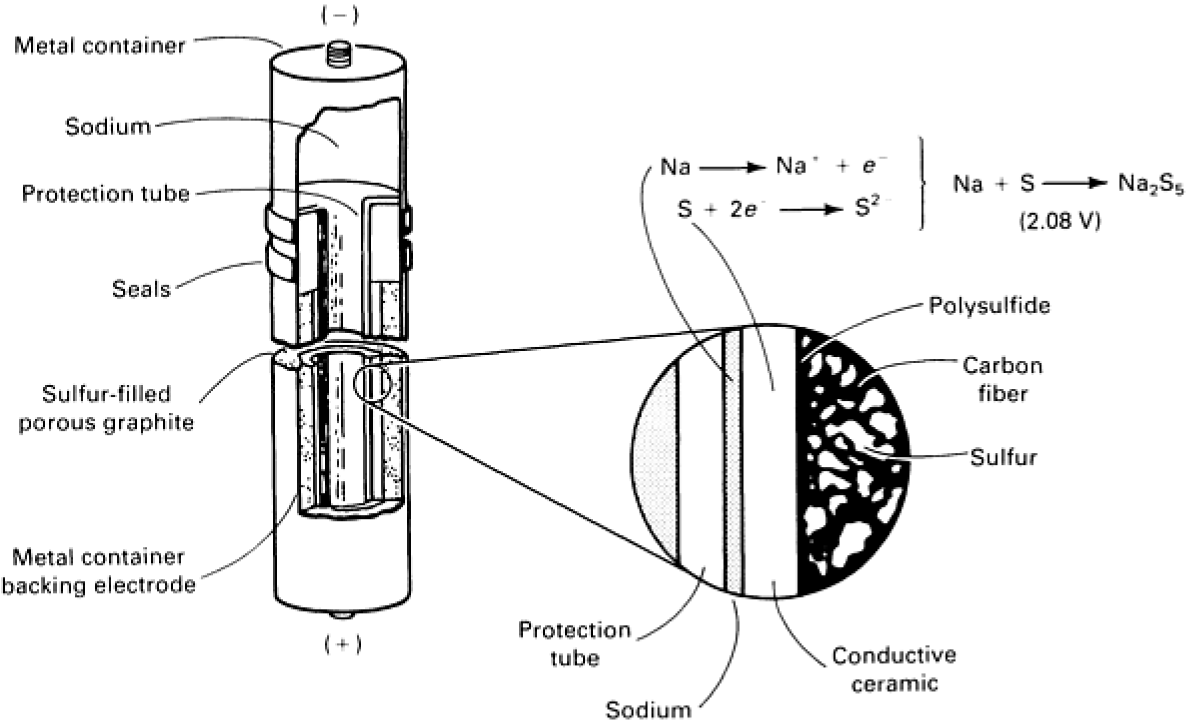

Fig. 2 Schematic of a sodium-sulfur cell. Source: Ref 58

Of the large number of metals and alloys that have been tested for compatibility with the sulfur electrode environments, few have shown both good corrosion resistance and high electrical conductivity. Carbon and graphite are corrosion resistant and have been used as positive current collectors in the central-sulfur cells; their relatively low electronic conductivity, however, limits cell length if good cell performance is to be maintained at high charge/discharge rates (Ref 60, 61, 62). Molybdenum (Ref 60, 63), high-chromium stainless steels, and nickel-base superalloys (Ref 64, 65, 66, 67, 68, 69, 70) have been used as cell containers/positive current collectors in central-sodium cells. None of these materials is satisfactory for production cells because of high cost and high density. Molybdenum is excellent for corrosion protection, but is difficult to fabricate and weld. Although molybdenum has been used as a liner for stainless steel cans (Ref 68), recent tests have shown its performance as a liner to be unacceptable (Ref 59). The corrosion resistance of the high-chromium alloys is marginal, with corrosion rates markedly increasing when the polysulfides are present (Ref 71, 72). The extensive formation of partially soluble corrosion products, such as Na_3FeS_3, NiS_2, and $NaCrS_2$ (Ref 71, 72), will reduce the amount of sulfur available for cell operation (thus reducing cell capacity) and possibly also affect cell chemistry and performance (Ref 73, 74). Also, post-test analysis of cycled cells has shown that $NaCrS_2$ has a tendency to accumulate at the electrolyte/polysulfide interface (Ref 75).

The most successful approach to the materials problem has been the use of protective coatings on a stainless steel or low-carbon steel substrate. Of the coating materials examined, chromium is by far the most studied and the most widely used in cell construction and testing (Ref 63, 76, 77, 78, 79). The corrosion rates for these chromium coatings, however, are

such that cell lifetimes much in excess of 5 years cannot be expected. This is adequate for an electric-vehicle battery, but is unsatisfactory for load-leveling applications for electric utilities. Other metal coatings, such as molybdenum (Ref 68, 80); alloy coatings based on the Co-Cr-Al-Y system (Ref 81); and electronically conducting refractory coatings, such as various carbides, nitrides, and oxides (Ref 80, 82, 83, 84, 85), are being researched as possible solutions to the materials problem.

Fuel Cells

This discussion will consider two types of fuel-cell technology whose state of development has advanced to the point at which reliability and service life are important issues in the evolution to a commercial product. Corrosive degradation of the components is now known to be a key factor in both the reliability and the service lives of these power plants. Because the two types of fuel cells use different families of materials to form the basic components, the two technologies will be discussed separately. The discussion will concern only corrosive degradation of the electrochemical energy conversion section of the power plant, omitting the fuel conditioning, thermal management (heat exchangers), and power-conditioning sections.

Phosphoric Acid Fuel Cell (PAFC)

The basic repeating elements is the electrochemical energy conversion section of the PAFC are shown schematically in Fig. 3. The repeating elements forming a single electrochemical cell are stacked to form a multicell module connected electrically in series. With the exception of the catalyst in the electrodes, the materials in the repeating elements are nonmetallic and are primarily allotropic forms of elemental carbon.

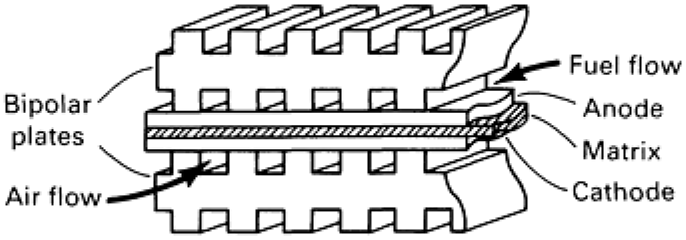

Fig. 3 Schematic of the repeating components of the PAFC power generation section

The basic structural component in the PAFC stack is the bipolar plate, which channels the gas flows across the backsides of the anode and cathode and also carries the electrical current from one cell to the next. The bipolar plate is a graphite-carbon composite fabricated by heat treating a graphite powder impregnated with hydrocarbon resin (Ref 86). Pyrolysis of the resin generally produces a glassy carbon second phase as opposed to the graphitic second phase (Ref 87) characteristic of synthetic graphite produced from coke-pitch (Ref 88) processing. The electrodes have a bi-layer composite structure, with a porous gas-supplying substrate layer fabricated from graphite fibers supporting the catalyst layer, which is a high-area carbon black impregnated with microcrystallites (2 to 10 nm) of platinum (Ref 89). A fluorocarbon polymer, such as polytetrafluoroethylene (PTFE), is used as a binder and wet-proofing agent in the electrode structure. The electrolyte, very concentrated H_3PO_4 (95 to 99%), is retained in a matrix of silicon carbide powder. The operating conditions for PAFCs vary, depending on the application and the size of the unit, from 478 K at 300 to 500 kPa (44 to 73 psi) to 433 K at ambient pressure. The pressurized operating conditions are more corrosive because of the higher temperature and the higher water activity.

At the anode, hydrogen is electrochemically converted to solvated protons by the reaction:

$$H_2S + 2S \rightleftharpoons 2(HS)^+ + 2e^- \qquad \textbf{(Eq 12)}$$

where S = H_2O, H_3PO_4. Oxygen is consumed at the cathode by reaction with solvated protons to form water by the reaction:

$$2(HS)^{+} + \frac{1}{2}O_2 + 2e^{-} \rightleftharpoons H_2O + 2S \qquad \textbf{(Eq 13)}$$

The primary corrosion reactions are the anodic oxidation of the various allotropic forms of carbon and the dissolution of platinum (probably to form complexed platinum ion, Pt^{2+}, in solution). The following generic cell reaction is representative of the carbon oxidation:

$$C + 2H_2O + 4S \rightleftharpoons CO_2 + 4(HS)^{+} + 4e^{-} \qquad \textbf{(Eq 14)}$$

Graphite is the most corrosion-resistant allotropic form of carbon. It is easily shown that the galvanic corrosion of graphite in oxygen-saturated acid is limited by the kinetics of he cathodic half-reaction, which is oxygen reduction on the graphite surface. However, if the surface of the graphite is both electronically and ionically coupled to an oxygen reduction catalyst, such as platinum, then the kinetics of the anodic half-reaction are controlling. This latter condition is clearly seen to be the case in the fuel-cell cathode because all components are in electrical contact, and at some points of physical contact, the components are wetted with electrolyte and share ionic pathways with the platinum crystallites. Extensive postmortem analyses have documented these corrosion-susceptible regions. Material loss, as a fraction of the material initially present, is greatest in the catalyst layer, followed by the losses in the substrate and then loss from the bipolar plate. This ranking is what would be expected based on relative surface area and extent of electrolyte wetting of the different components, assuming that the intrinsic corrosion resistance of each component is the same.

Reasonably extensive comparative studies of the kinetics of anodic oxidation of the various allotropic forms of carbon have been conducted. For example, a fairly extensive study of the corrosion of candidate high-area carbon blacks for use in the catalyst found that a correlation exist between corrosion rate (on a unit area basis) and *c*-axis layer plane spacing determined by x-ray powder diffraction analysis of heat-treated furnace blacks (Ref 90). Furnace blacks graphitized by heat treatment at 3000 K appear to be the material of choice for this component. Corrosion rates for graphite fiber materials were also compared with those of graphitized furnace blacks; on a unit area basis, the rates were found to be equivalent (same order of magnitude).

In addition, extensive studies of the corrosion of various types of carbon composite materials used in the bipolar plate have been reported in which the progressive development of corrosion resistance in the resin phase was followed by using thermal treatment (Ref 91). Lastly, the only fundamental study of the kinetic parameters of the corrosion reaction using single-phase materials, such as glassy carbon and single-crystal graphite, is discussed in Ref 92. This study confirmed three suggestions from previous work: that graphite is the most corrosion-resistant form of carbon (with the possible exception of diamond and diamondlike forms, which are electrically nonconductive and generally considered to be unsuitable), that the basal plane of graphite has mush higher corrosion resistance than the edge-plane, and that the corrosion rate is first-order in water activity.

Platinum corrosion (dissolution to solvated ions) is also a serious problem in PAFCs. In one investigation, the solubility of bulk platinum was measured in concentrated H_3PO_4 at 443 and 463 K (Ref 93). The potential dependence of the solubility was found to be $RT/2F$, consistent with the Nernst equation for Pt/Pt^{2+} (as opposed to Pt/Pt^{4+}). Using these data, another researcher showed that platinum dissolution becomes rapid for cell voltages above 0.8 V and will result in loss of platinum from the cathode and precipitation at the anode (Ref 94). Platinum corrosion is a phenomenon for which there appears to be no remedy other than operating the fuel cell in such a way as to avoid cathode potentials above about 0.8 V for extended periods of time.

Molten Carbonate Fuel Cell (MCFC)

The MCFC component assembly follows the bipolar principle of the PAFC stack, but it uses completely different materials. Figure 4 shows a schematic diagram of the basic repeating elements in an MCFC stack. The electrolyte is a molten lithium carbonate (Li_2CO_3), potassium carbonate (K_2CO_3, and/or sodium carbonate (Na_2CO_3) mixture, with the most commonly chosen composition being 62Li_2CO_3-38K_2CO_3 (usually referred to as a tile because the carbonate salts and the aluminate powder are hot pressed to form a solid piece) at 923 K. The ionic current in the cell is carried by the carbonate ion (CO_3^{2-}); therefore, the half-cell reactions at the anode and cathode are different from their PAFC counterparts. In this case, the cathode reaction is the reduction of oxygen by reaction with carbon dioxide (CO_2) to form CO_3^{2-}:

$$\frac{1}{2}O_2 + CO_2 + 2e^- \rightleftharpoons CO_3^{2-} \quad \textbf{(Eq 15)}$$

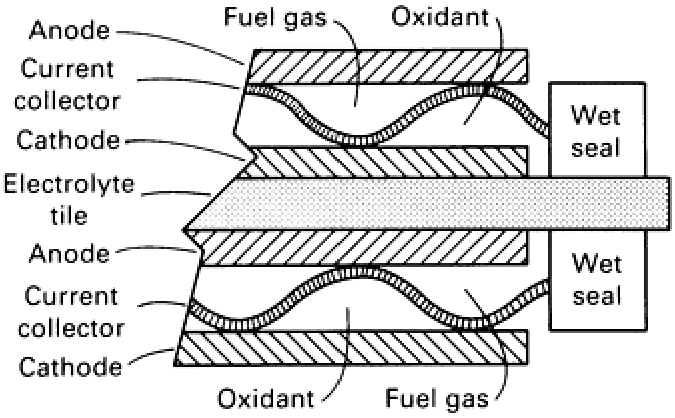

Fig. 4 Schematic of the repeating components of the MCFC power generation section

At the anode, hydrogen reacts with the CO_3^{2-} ion to form CO_2 and water:

$$H_2 + CO_3^{2-} \rightleftharpoons H_2O + CO_2 + 2e^- \quad \textbf{(Eq 16)}$$

To maintain invariance in electrolyte composition with time, it is necessary to recycle CO_2 from the anode gas to the cathode gas streams continuously. The current collector material is typically a high-chromium stainless steel, and the electrodes are nickel-base materials (metallic porous nickel at the anode and porous nickel oxide, NiO, at the cathode).

The components subject to corrosion and the nature of the corrosion processes are reasonably well understood from postmortem analyses of tested cells. With type 316 stainless steel as the current collector, moderate-to-severe attack of the anode current collector was observed after a few thousand hours of operation, with much less attach observed at the cathode (Ref 95). The region of the current collector that was most severely attacked was the point of contact with the anode material (and thus in contact with the carbonate melt) and areas near the point of contact, probably owing to creep of carbonate onto the current collector.

Early cells showed severe attack in the region of the wet-seal, a component that seals the anode from the external ambient gas (Ref 95). The wet-seal corrosion problem appears to have been solved by use of an aluminum coating on the collector housing that forms a dense insulating layer of Al_2O_3 that breaks the ionic path between the housing surface and the electrolyte and prevents galvanic corrosion (Ref 96).

A more serious and as yet unsolved corrosion process is the finding of significant solubility of NiO in the carbonate melts in use. Early theoretical analysis of metal corrosion in molten alkali carbonates presumed that NiO dissolution occurs by the reaction (Ref 97):

$$NiO + CO_2 \rightleftharpoons Ni^{2+} + CO_3^{2-} \quad \textbf{(Eq 17)}$$

This analysis also predicted that NiO solubility would increase in proportion to CO_2 pressure. In the early period of MCFC technology development, it was believed that the CO_2 partial pressure at the cathode would be within a range in which NiO dissolution would not be significant. A more recent theoretical analysis of NiO dissolution (Ref 98) and experimental results (Ref 99) have shown the importance of other dissolution reactions for NiO, particularly those involving the formation of soluble anions according to:

$$NiO + \frac{1}{2}Li_2CO_3 + \frac{1}{2}O_2 \rightleftharpoons \quad \textbf{(Eq 18)}$$

$$NiO_2^- + \frac{1}{2} CO_2 + Li^+$$

$$NiO + Li_2CO_3 = NiO_2^{2-} 2Li^+ + CO_2 \qquad \textbf{(Eq 19)}$$

Equation 6 predicts an oxygen partial pressure dependence for NiO solubility that would enhance solubility with pressurization of the reactant gases. Recent measurements of NiO solubility and transport in the electrolyte tile have been reported (Ref 100). Nickel oxide solubility is now recognized as a serious technical problem for MCFC technology, and alternative cathode materials are being sought (Ref 5).

General corrosion studies of simple metals and selected alloys in molten carbonate melts date back to the earliest time of interest in MCFC technology. A relatively recent bibliography on molten salt corrosion covers several types of molten salts in addition to carbonates and provides a useful index to the literature before about 1976 (Ref 101). Reference 102 contains a section on carbonates and includes references from the Russian literature. Work that addresses corrosion phenomena specific to MCFC technology is much less plentiful. The theoretical overview of the requirements for corrosion resistance in MCFC applications provided in Ref 103 has served as a guide for much of the recent work.

Corrosion of Metallic Implants and Prosthetic Devices

Anna C. Fraker, National Bureau of Standards

Introduction

BIOMEDICAL PROSTHETIC DEVICES are artificial replacements that are used in a biological system, such as the human body, in an effort to provide the function of the original part. Prosthetic devices are made of polymeric, metallic, and ceramic materials or combinations of these materials, depending on the intended use. There are specific degradation processes for all of these materials. Metals are used as surgical implants in the human body primarily for orthopedic purposes. Additional applications include reconstructive surgery, cosmetic surgery, wire leads, heart valve parts, aneurysm clips, and dental uses (see the article "Tarnish and Corrosion of Dental Alloys" in this Volume).

The first requirement for any material to be placed in the body is that it should be biocompatible and not cause any adverse reaction in the body. The material must withstand the body environment and not degrade to the point that it cannot function in the body as intended. For example, metals used in the cardiovascular system must be nonthrombogenic, and in general, the more electronegative the metal with respect to blood, the less thrombogenic the metal will be. Cobalt-chromium alloys of the HS-21 and HS-25 compositions and titanium are used in heart valves. Design also is an important factor in preventing thrombus formation. Corrosion is included in the topic of biocompatibility because it is an important factor in the release of metal ions into the body environment and in the degradation of the implant metal. *In vitro* electrochemical measurements can be conducted in controlled environments, and these techniques provide methods of determining the basic corrosion reactions necessary for predicting the corrosion behavior of materials and for screening and characterizing materials intended for use in surgical applications.

This article will discuss the corrosion of metallic materials. Background information will be given on the metals used in prosthetic devices, biocompatibility, significance of corrosion, and standards. This will be followed by discussions of electrochemistry and corrosion processes, the types of corrosion to be expected, and the test methods used to evaluate the corrosion behavior of surgical implant metals. Information on specific materials and on corrosion processes is provided in other articles in this Volume and in the references cited in this article.

Background

The earlier attempts at repairing the human body probably went unrecorded. There are a number of historical accounts of the development of the use of metals in the human body (Ref 1, 2, 3, 4, 5). The first record of metal implantation discusses the repair of a cleft palate with a gold plate by Petronius in 1565 (Ref 1, 3). About 100 years later, Hieronymus Fabricius described the use of gold, iron, and bronze wires for sutures. In 1775, arguments arose between Pujol, a surgeon opposing internal fixation, and Icart, a surgeon who favored internal fixation and used brass wires (Ref 1, 3, 6). Icart encountered problems with infection, but cited the work of two French surgeons, Lapeyode and Sicre, who had successfully used wire to repair bone fractures. In 1886, Hansmann used metal plates for internal fixation (Ref 7). These plates, which were nickel-plated steel, had holes through which screws were inserted into the bone. Some had a bend at one end and protruded through the skin for ease of removal. X-rays were discovered by Roentgen in 1895. The use of x-rays to observe the healing of fractures revealed the advantages of internal fixation and stimulated its use.

It was difficult in early times to determine whether the infection and inflammation were due to the metal or to other factors. The development of aseptic techniques by Baron Joseph Lister in the 1860s made it possible to determine the most suitable metals for use as implants (Ref 1, 8). As the success of surgery increased, it became clear that the metals were an important limiting factor. The metals tested for implant use included platinum, gold, silver, lead, zinc, aluminum, copper, and magnesium (Ref 1); all of these were found to be too malleable. Magnesium was found to be highly reactive in the body. Steel plates coated with gold or nickel came into use. The need for strong and corrosion-resistant metals became apparent. Stainless steels were introduced as implants in 1926, and cobalt-chromium-molybdenum-carbon alloys were first used in 1936 (Ref 2). Titanium was determined to be inert in the body (Ref 9, 10); titanium and titanium alloys

were not introduced until the 1960s and came into increased use in the 1970s. Tantalum, which was studied in the early 1950s, does show some tissue reaction (Ref 11, 12).

Observations eventually led to the discovery of electrochemical reactions in the body in the 1930s. Steel screws in a magnesium plate produced the dramatic result of having the magnesium plate disappear before the fracture healed. The combination of copper with zinc was found to be highly reactive, as was the combination of brass screws with an aluminum plate. Surgeons and scientists began to believe that homogeneous metals should be used to prevent these reactions. At this time, many scientists were beginning to notice electrochemical reactions with surgical implants; one of the first actual measurements of an electrode potential difference between uncorroded and corroded areas of screws was made by F. Masmonteil (Ref 13). C.S. Venable, W.P. Stuck, and A. Beach are responsible for bringing electrolytic effects to the attention of surgeons and scientists in the United States (Ref 14). This interest in and discovery of electrochemical effects with surgical implants in the 1930s occurred more than 140 years after Italian physician Luigi Galvani published his electrochemical discoveries (Ref 15). Electrochemistry was already a well-established science. A. Volta showed that the electricity was generated by the contact of dissimilar metals, not from "animal electricity," as stated by Galvani (Ref 15). Galvani did later demonstrate the electrical nature of nerve action.

The latter half of the 20th century has seen marked advances in the successful use of prosthetic devices. The success of the total hip prosthetic increased because of the addition of the acetabular component (hip socket) and the surgical procedures introduced by J. Charnley (Ref 16) and others, who used poly methylmethacrylate bone cement to affix the metal femoral component and ultrahigh molecular weight polyethylene acetabular cup. Biomaterials research was promoted by the founding of the Society for Biomaterials in 1974 and by increased interest among other medical and scientific societies. More emphasis was placed on standards and specifications, and the American Society for Testing and Materials (ASTM) established Committee F-4 on Medical Materials and Devices in 1964 (Ref 17). Congress passed the Medical Device Amendments (Ref 18) and placed responsibility for the implementation of this legislation with the United States Food and Drug Administration.

J.S. Hirschhorn and J.T. Reynolds explored the use of a totally porous cobalt-chromium-molybdenum implant that had an elastic modulus closer to that of bone, but the porosity made the strength insufficient for the load (Ref 19). Metal porous coated implants were introduced, and they provided a porous coating for bony ingrowth attachment and maintained the strength of the solid substrate (Ref 20, 21, 22, 23, 24). Hydroxyapatite filter within the porous coating increases bone growth during the first 4 weeks (Ref 24). Electrical stimulation also increases the early stages of bone ingrowth (Ref 25, 26). Corrosion of porous coatings is a concern because of the increased surface area and the changed surface morphology. E.P. Lautenschlager (Ref 27) studied the corrosion of porous Ti-6Al-4V, and H.V. Cameron (Ref 28) studied porous cobalt-chromium. Corrosion studies of porous Ti-6Al-4V and cobalt-chromium-molybdenum indicated no changes in corrosion behavior except for increased current due to the increased surface area of the porous materials; however, caution should be exercised regarding possible contamination or crevice corrosion due to porous configurations (Ref 23, 29).

Metals and Alloys

Metals and alloys used as implants undergo an active-passive transition; therefore, corrosion resistance results from the growth of a protective surface film. These metals are in the passive state with a protective surface oxide film when used as implants and are highly corrosion resistant in saline environments. The metals currently used for surgical implants include stainless steel (AISI type 316L), cobalt-chromium-molybdenum-carbon, cobalt-chromium-tungsten-nickel, cobalt-nickel-chromium-molybdenum, titanium, Ti-6Al-4V, and tantalum. The compositions and mechanical properties of these metals and alloys as recommended by ASTM (Ref 17) are given in Tables 1 and 2.

Table 1 Compositions of metals and alloys currently used as surgical implants

Metal or alloy	Composition[(a)]

(a) Subject to agreement between purchaser and manufacturer.

The metals and alloys most frequently used as implant materials will be discussed in terms of metallurgical factors to provide a better understanding of their effect on corrosion resistance. For example, small changes in alloying additions of certain elements can result in significant changes in corrosion behavior. Such microstructural changes as grain size, precipitates, location of precipitates, and the presence of impurities can be important. Additional information on the metallurgical aspects is available in the article "Introduction to Metallurgically Influenced Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, the article "Failures of Metallic Orthopedic Implants" in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook,* and Ref 5, 30, and 31.

Stainless Steels. Steels and coated steels were used in the early 1900s for surgical purposes (Ref 1, 2, 3). The Frenchman Berthier is credited with discovering in 1821 that adding chromium to iron greatly improves corrosion resistance (Ref 32). Stainless steel was introduced in 1912 (Ref 33). In 1926, type 302 and other stainless steels were used in orthopedic surgery, and type 316 stainless steel came into use during World War II (Ref 3).

Type 316L is used most widely in applications in which the implant is temporary, although it is also used for some permanent implants. The composition and mechanical properties are given in Tables 1 and 2, respectively. Type 316L is the least corrosion resistant to body fluids of the implant metals discussed, but its corrosion resistance is adequate for some purposes, and if the material is in the cold-worked condition, the mechanical properties are good. Figure 1 shows type 316L stainless steel in the cold-worked condition. Deformation lines are evident, indicating that the material is work

hardened. This material is virtually free of inclusions. Inclusions often contain sulfur, which is detrimental to pitting corrosion resistance.

Fig. 1 Microstructure of cold-worked AISI type 316L stainless steel. Etchant: 20 mL HCl, 10 mL HNO_3, and 3 g $FeCl_3$ for 2 to 5 s

The effects of alloying are important when variations in steels are under consideration. Iron exists in two different crystal structures (Ref 34), but there are two structure transitions as the structure transforms from the high-temperature body-centered cubic (bcc) δ-ferrite at 1390 °C (2534 °F) to the face-centered cubic (fcc) γ-austenite, which in turn transforms to bcc α-ferrite at 910 °C (1670 °F):

$$\text{bcc } \delta\text{-iron} \xrightarrow{1390\ ^\circ\text{C}} \text{fcc } \gamma\text{-iron} \xrightarrow{910\ ^\circ\text{C}} \text{bcc } \alpha\text{-iron}$$

Details of the metallurgy of stainless steels used for surgical implants are available in Ref 32. Chromium, which is the key element in the corrosion resistance of stainless steel, is a ferrite former. Carbon is an austenite stabilizer. Nickel is added to steel to stabilize the austenite phase. Austenitic stainless steels, such as type 316L, contain chromium and nickel. The minimum combined content of these elements is 23%; the minimum chromium content is 16%, and the minimum nickel content is 7%. Other austenitic stainless steels used widely in industry are types 302, 303, and 304. The type 316L stainless steel used for surgical implants contains 17 to 19% Cr and 12 to 14% Ni.

Molybdenum is added in amounts of 2 to 3% to strengthen the protective surface film in saline and acidic environments and to increase resistance to pitting. Molybdenum in amounts above 3% can reduce the corrosion resistance to strongly oxidizing environments and can result in the formation of some ferrite.

Carbon content in the type 316L surgical implant stainless steel should not exceed 0.08%. The greatest corrosion resistance is obtained when the carbon is in solid solution and when there is a homogeneous single-phase structure. A homogeneous austenitic structure can be produced by heat treating type 316L in the range of 1050 to 1100 °C (1920 to 2010 °F) and cooling rapidly. This rapid cooling (water quenching for large pieces) is essential for keeping the carbides in solution. Slower cooling allows chromium carbides to form at the grain boundaries and leaves the steel susceptible to intergranular corrosion. There is a depletion of chromium in areas adjacent to the grain-boundary carbides, and this further enhances corrosion in grain boundaries. The formation of these grain-boundary carbides in stainless steels is known as sensitization. The susceptibility of low-carbon stainless steels to sensitization is less than that of stainless steels with higher carbon contents.

When carbon is added to stainless steels containing little or no nickel and the stainless steel is heat treated, the result is the formation of tetragonal martensite, a nonequilibrium hard needlelike phase. Martensitic stainless steels are part of the type 400 series, which are not used for surgical implants.

Austenitic stainless steels are not ferromagnetic, they work harden easily, and corrosion resistance is acquired by the presence of a surface film. Magnetic alloys should not be used in the body, because they could become dislodged in a magnetic field. Ferrite should not be present in implants, not only from the standpoint of its corrosion resistance but also because it is magnetic. Magnetic-resonance imaging should not be used for an individual with any type of magnetic material in his body, and if possible, it should be avoided for any patient who has a metallic implant. Two possible problems are the heating of the metal and the distortion of position produced by the metal even though it is not magnetic.

The corrosion resistance of stainless steel can be improved by electropolishing. Electropolishing provides a uniform surface, removes surface defects that could serve as pit sites, and leaves a protective surface film. Another method of improving corrosion resistance is the development of a protective film by passivating the steel in a 20- to 40-vol% nitric acid (HNO_3) solution at 60 °C (140 °F) for 30 min (Ref 35).

Cobalt Alloys. Cobalt-chromium alloys were first studied in 1895 by E. Haynes (Ref 36, 37), who received U.S. Patents in 1907 for a cobalt composition range of 49 to 90% (Ref 38, 39). A report on the alloys appeared in 1913 (Ref 40). Since that time, cobalt-chromium alloys have been further developed and have been used in applications ranging from aircraft engines to surgical implants. The alloys are noted for high strength, good corrosion resistance, and good wear resistance. The influence of refractory metal additions or strengthening, carbide formation, and intermetallic compound formation is discussed in Ref 41. The cobalt-chromium alloys are used for surgical implants in both the cast and wrought forms, which are typified, respectively, by Haynes Stellite-21, a cobalt-chromium-molybdenum-carbon alloy, and Haynes Stellite-25, a cobalt-chromium-tungsten-nickel alloy. The cobalt-chromium alloys have various trade names.

Cobalt undergoes a structure transformation at 450 °C (842 °F) and is fcc above this temperature and hexagonal close-packed (hcp) below it (Ref 34). Mixtures of both structures usually exist at room temperature. The cobalt-chromium alloys are strengthened by solution hardening with refractory metals (elements such as molybdenum or tungsten) and by the addition of carbon to form carbide phases that strengthen the material by dispersion hardening and grain-boundary stabilization (Ref 41). The main carbide found in the alloys is $Cr_{23}C_6$, but other carbides, such as Cr_7C_3 and M_6C, are also present. The role of carbide phases in strengthening the material is discussed in Ref 42 and 43. Agglomeration or large amounts of these phases can reduce fatigue life. The nickel addition to the wrought material stabilizes the fcc phase and increases ductility. Normally, in the cast HS-21 material, both hexagonal (ϵ) and cubic (α) forms of cobalt can be present, along with some σ phase.

Typical microstructures of the cast, wrought, forged, high-strength, and hot isostatically pressed materials are shown in Fig. 2, 3, 4, 5. The cast material shown in Fig. 2 has large grains with an interdendritic phase consisting of carbides, cobalt, and σ phase. Voids in cast materials can make the materials weaker. The size and shape of the grain and the location and amount of the carbides depend on the manner of casting and the rate of cooling. Thermomechanical treating of the cast material and annealing at 1065 °C (1950 °F) for 30 min will result in some improvement in mechanical properties (Ref 44).

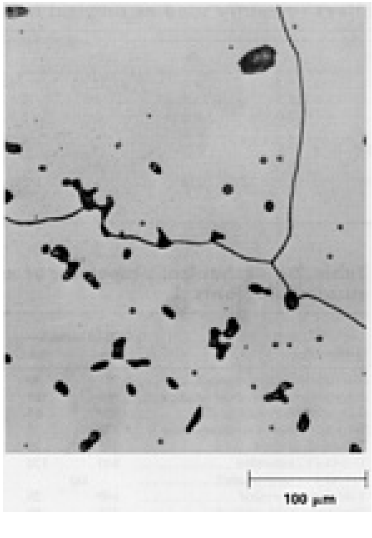

Fig. 2 As-cast microstructure of cast cobalt-chromium-molybdenum alloy. Etchant: 20 mL HCl, 10 mL HNO_3,

and 3 g $FeCl_3$ for 30 to 60 s

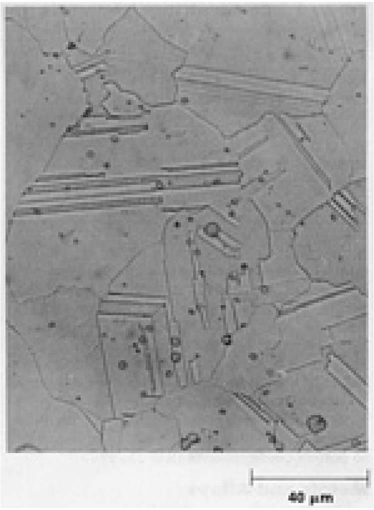

Fig. 3 Microstructure of wrought cobalt-chromium-nickel-tungsten alloy. Electrolytic etch: 100 mL HCl and 0.5 mL H_2O_2 at 6 V for 10 s

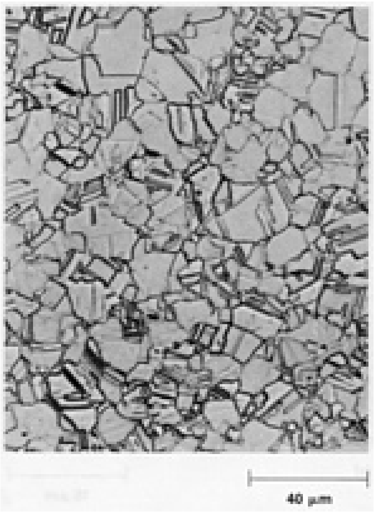

Fig. 4 Microstructure of forged high-strength cobalt-chromium-molybdenum alloy. Etchant: 20 mL HCl, 10 mL HNO_3, and 3 g $FeCl_3$ for 30 to 60 s

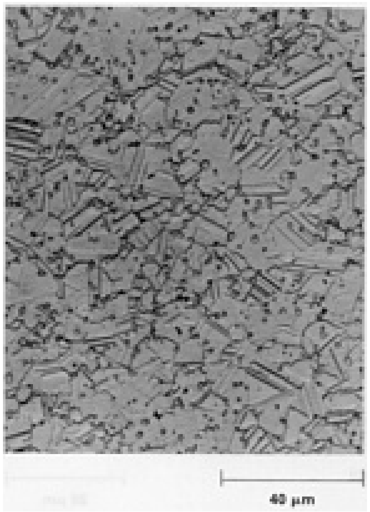

Fig. 5 Microstructure of hot isostatically pressed cobalt-chromium-molybdenum alloy. Etchant: 20 mL HCl, 10 mL HNO_3, and 3 g $FeCl_3$ for 30 to 60 s

Figure 3 shows the wrought material of the HS-25 composition. This material is strengthened by deformation, twinning, and small grain size. The forged high-strength alloy shown in Fig. 4 is closely related to the cast material (Fig. 2) in terms of composition. This material has been forged in a manner to produce a small, fine grain size and increased mechanical strength. The hot isostatically pressed material shown in Fig. 5 has a small grain size, a fine dispersion of carbides, and improved mechanical properties.

Porous materials are used as prosthetic devices when there is a need for attachment by ingrowth of soft or hard tissue. In one study, a cobalt-chromium alloy was sintered to produce a material with 30% porosity (Ref 19). This lowered the elastic modulus of the material, but the material was too weak. Another researcher sintered cobalt-chromium-molybdenum-carbon spheres to the surface of a substrate of the same material (Ref 21). This technique is used for the production of prosthetic devices. One problem associated with the production of cobalt-chromium-molybdenum-carbon sintered porous coatings that are sintered in the 1150- to 1300- °C (2100- to 2370- °F) range is the formation of carbide phases during sintering and cooling. An example of the sintered spheres on a solid substrate is shown in Fig. 6.

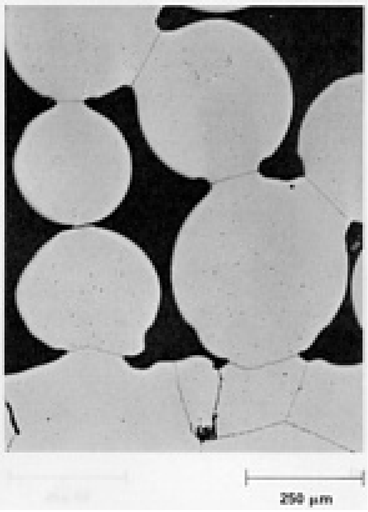

Fig. 6 Microstructure of sintered porous coated cobalt-chromium-molybdenum alloy. Etchant: 20 mL HCl, 10 mL HNO_3, and 3 g $FeCl_3$ for 30 to 60 s

One extensive study of this problem investigated the relationship-of microstructure to mechanical properties of the cobalt-chromium-molybdenum-carbon alloy (Ref 45). These studies of heat treating, cooling, microstructures, and mechanical properties showed that there are two methods of reducing the grain-boundary interdendritic and/or carbide phases responsible for decreasing ductility and ultimate tensile strength. The first method--cooling the material from a temperature above 1508 K to a temperature below 1508 K, then quenching--is not very practical, and the second method--reducing the carbon content to levels below 0.17%--results in a large decrease in yield strength. In addition, replacing some carbon by nitriding the alloy was found to increase yield strength (Ref 45, 46).

Alloy MP35M (35Co-35Ni-20Cr-10Mo), a cobalt-nickel alloy, has been used for surgical implants in recent years (Ref 47). Figure 7 shows the microstructure of this alloy in the hardened but aged condition. This material is strengthened by phase transformations induced by deformation, and it has yield strength values ranging from 414 MPa (60 ksi) for annealed material to 2128 MPa (309 ksi) for work-hardened and aged material. Work hardening involves the transformation of an fcc crystal structure to an hcp structure. Aging for 4 h in the 427- to 649- °C (800- to 1200- °F) range results in the precipitation of Co_3Mo and further strengthens the alloy; Co_3Mo has a hexagonal crystal structure and is formed by a peritectic reaction at 1020 °C (1868 °F).

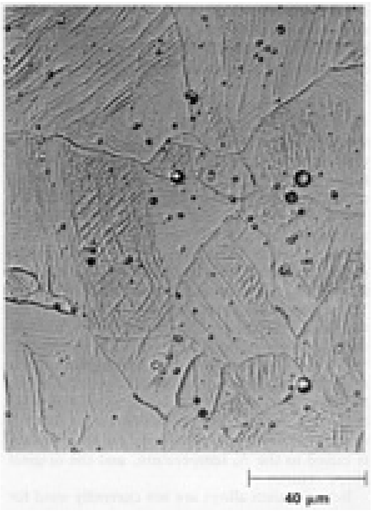

Fig. 7 Microstructure of MP35N cobalt-nickel-chromium-molybdenum alloy. Electrolytic etch: 80 mL $HC_2H_3O_2$ and 20 mL HCl at 6 V for 5 to 60 s

Titanium and titanium alloys are relatively new materials compared to steels and cobalt-chromium alloys. Titanium was discovered in 1790 (Ref 48). The ninth most common element in the earth's crust, titanium, occurs as the minerals rutile (TiO_2) and ilmenite ($FeO \cdot TiO_2$), with $FeO \cdot TiO_2$ being found in larger deposits. Titanium is at least as strong as steel and is about 50% lighter. This high strength-to-weight ratio has made titanium and its alloys attractive materials for use in aircraft, aerospace, and marine applications.

Titanium is easily fabricated, but contamination with such interstitial elements as hydrogen, nitrogen, and oxygen should be avoided, because these elements have an embrittling effect on titanium. The development of the Kroll process in 1936 for extracting the metal and producing titanium sponge made it possible to produce the metal in commercial amounts (Ref 49); by 1948, it was commercially available in the United States. The Kroll process involves the chlorination of the ore to produce titanium tetrachloride ($TiCl_4$), which is reduced with magnesium metal in a sealed reactor with an inert atmosphere. Magnesium chloride ($MgCl_2$) is drained from the reactor vessel, leaving titanium sponge. The sponge is contaminated with ferric chloride ($FeCl_3$) and $MgCl_2$, which are then leached out. Purer titanium can be obtained by decomposing titanium tetraiodide (TiI_4) at high temperatures or by electrolytic reduction.

In the 1950s, titanium alloys were developed to answer the need for materials with high strength, low weight, high melting temperature, and high corrosion resistance for jet aircraft engines and airframe components. It was not until the 1960s that titanium alloys were used as surgical implant materials (Ref 10, 50, 51, and 52). Use of titanium alloys in surgery has been growing steadily since the mid-1970s and continues to increase. An ASTM symposium on the use of titanium for surgical implants was held in 1981 (Ref 53). Figure 8 shows the microstructures of pure titanium, Ti-6Al-4V,

and Beta III alloy (Ti-11.5Mo-6Zr-4.5Sn). Mechanical properties of the α-β alloys and the β alloys depend on such factors as heat treatment, quenching, and aging.

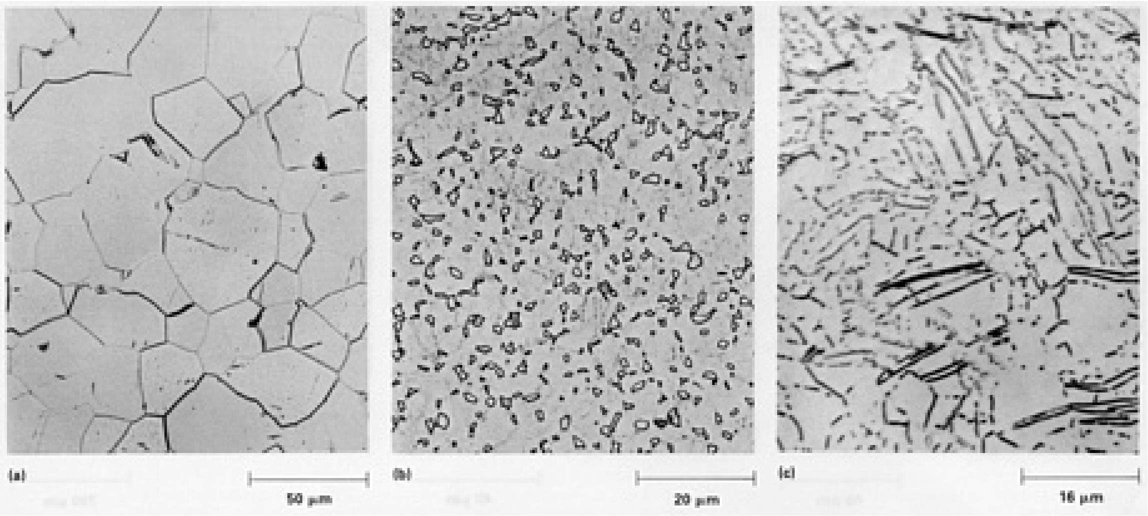

Fig. 8 Microstructures of titanium and titanium alloys. Kroll's etchant: 95 mL H_2O, 3.5 mL HNO_3, and 1.5 mL HF for 20 s. (a) Unalloyed titanium. (b) Ti-6Al-4V. (c) Beta III titanium.

Titanium undergoes an allotropic transformation from an hcp structure (α phase) to a bcc structure (β phase) at 882 °C (1620 °F) (Ref 31, 34). As a result of this structural change, titanium alloys fall into three classes: α alloys, α-β alloys, and β alloys. Selected alloying additions, such as aluminum, oxygen, tin, and zirconium, are α stabilizers, and other elemental additions, such as vanadium, molybdenum, niobium, chromium, iron, and manganese, are β stabilizers. Aluminum acts as an α stabilizer in amounts up to 8%, but aluminum compositions higher than this can result in an embrittling titanium-aluminum phase change. The presence of oxygen as an interstitial element is damaging to toughness.

In one study, porous surface coatings were applied to a solid substrate by using arc plasma spraying (Ref 20). An example is shown in Fig. 9. These coatings and their properties were studied further in another investigation (Ref 54). The pore size of the arc plasma sprayed coating can be varied or can be graduated throughout a given coating. Wire mesh porous coatings are available that are sintered together and then sintered to the substrate. Attempts at sintering spherical powders to titanium alloys have not been very successful until recently, because of the need to sinter at high temperatures. Alloy Ti-6Al-4V should not be sintered at temperatures above the β transus temperature, because mechanical properties, especially fatigue, are adversely affected.

Fig. 9 Microstructure of the arc plasma sprayed coating on porous coated Ti-6Al-4V. Kroll's etchant

A titanium-nickel alloy known as Nitinol is used in dentistry and has potential use when a high strain recovery is needed, such as for braces or restraining devices, or when the shape-memory effect of the alloy can be used. According to the shape-memory effect, an alloy wire that is shaped or bent at a given temperature and then reshaped at another temperature will return to the original shape when it is brought back to the shaping temperature. Other alloys, such as gold-cadmium and silver-cadmium, exhibit this effect (Ref 55).

The shape-memory effect is associated with a martensitic transformation. Shape memory can also occur when the alloy is already in the martensitic condition. In this case, it probably occurs through a rearrangement of the martensitic plates.

There are two temperatures of concern: the transformation temperature and the reverse transformation (A_s) temperature. The transformation temperature, M_s, below which the material transforms to martensite, for stoichiometric titanium-nickel is approximately 650 °C (1200 °F) (Ref 56). The M_s temperature can be lowered by changing the titanium-nickel ratio or by alloying with other elements, such as cobalt. An M_s temperature more compatible with the body can be achieved by alloying titanium-nickel with titanium-cobalt. The reverse transformation temperature, A_s, for titanium-nickel begins at 165.6 °C (330 °F), and that for titanium-cobalt starts at -237.2 °C (-395 °F). The desired shape (for example, a twist in a wire) that the memory will hold is fixed above the M_s temperature, the shape is changed as needed below the temperature transition range (for example, the wire is straightened), the temperature is raised to the A_s temperature, and the original shape returns.

Beta-titanium alloys are not currently used for surgical implants, but several implant producers are considering these materials. The β-titanium alloys are metastable and are produced by adding alloying elements in sufficient amounts to stabilize the high-temperature bcc structure at room temperature. The mechanical properties of the material depend on the morphology and structure of high-modulus α particles in the low-modulus β matrix. The material can be processed to have a high fracture toughness. There are two types of β stabilizers (Ref 57). The addition of such β stabilizers as molybdenum, vanadium, tantalum, and niobium results in the formation of isomorphous α-titanium from the metastable β. Beta stabilizers such as chromium, manganese, iron, silicon, cobalt, nickel, and copper result in the formation of a eutectoid mixture of α and a compound. The structure and properties of the material can be controlled by alloying and thermomechanical processing. Some β alloys are Ti-13V-11Cr-3Al, Beta III, Ti-3Al-8V-6Cr-4Mo-4Zr, Ti-10V-2Fe-3Al, Ti-15Mo-5Zr-3Al, and Ti-15V-3Al-3Sn-3Cr. Many other possibilities exist for alloying to produce the β structure.

Pure titanium is used in reconstructive surgery and for purposes not subject to high loads. Pure titanium is also used for coatings.

Significance of Corrosion

Corrosion of metal implants is critical because it can adversely affect biocompatibility and mechanical integrity. The material used must not cause any adverse biological reaction in the body, and it must be stable and retain its functional properties. Corrosion and surface film dissolution are two mechanisms for introducing additional ions to the body. Extensive release of metal ions from a prosthesis can result in adverse biological reactions and can lead to mechanical failure of the device.

Metals used in the human body must have a high corrosion resistance and must not be treated or used in a configuration that would degrade the corrosion behavior. Degradation of metals and alloys used as surgical implant orthopedic devices is usually a combination of electrochemical and mechanical effects. Because surgical implants are being placed in younger people and because the older population is living longer, demands on the materials for good long-term durability and corrosion resistance are increasing.

Biocompatibility is the first consideration for materials of any type that are to be used in the body (Ref 58). Various *in vitro* and *in vivo* tests have indicated that selected metals are biocompatible and suitable for use as surgical implants. The long-term effects of metal ions on the body are less well known. Data are being collected, and studies continue in an effort to provide more information. It is desirable to keep metal ion release at a minimum by the use of corrosion-resistant materials. Some effects of incompatible materials include interference with normal tissue growth near the implant, interference with systemic reactions of the body, and transport and deposit of metal ions at selective sites or organs. There is always concern about the carcinogenic effects of foreign materials in the body, both short-term and after periods exceeding 20 years.

The first investigation of tissue tolerance to metals was made by studying wires implanted in dogs (Ref 59). Platinum was concluded to be the least irritating of the platinum, gold, silver, and lead tested. Biocompatibility testing was conducted by implanting metals in rabbits (Ref 60). Minimal tissue reaction was reported to cobalt-chromium alloys, type 316L stainless steel, and titanium. Some tissue reaction was credited to the size and shape of the implant. Some individuals are sensitive to metals, and some develop metal sensitivity at a later time after receiving an implant. Stainless steel implants sometimes cause rashes or pain; this is because of nickel ion release. Metal sensitivity is discussed in Ref 61.

Integrity of the Device. Orthopedic devices must maintain mechanical strength. Load-bearing implants at the lower extremities must support three or four times the body weight. Resistance to cyclic loading is important because the metal would probably be subjected to more than 3×10^6 cycles per year. Corrosion can lead to mechanical failure of the device.

Surface Effects and Ion Release

Metal ion release from surgical implants probably results primarily from corrosion. Another source of metal ions is passive films, which are thick and not stable in body fluids. Titanium is highly corrosion resistant, yet ion release occurs. Titanium ion release is discussed in Ref 62. Titanium that is subjected to various surface treatments comes to the same rest potential in saline solution, indicating that changes have taken place in the surface film (Ref 63). The effects of passivation and sterilization have been studied. Films placed by these methods on stainless steel and cobalt-chromium alloys reduced corrosion currents, but the effects were negligible with Ti-6Al-4V (Ref 64). In all cases, surface films exist that must be stable in the body or must change to a stable form. Metal ion release and retention of ions in the body are discussed in Ref 64, 65, 66, and 67.

Standards

The American Society for Testing and Materials instituted the F-4 Committee on Medical Devices and Materials. Task forces associated with this committee have developed 106 approved documents that appear in Ref 17. These documents include specifications for implant metals in terms of composition, mechanical properties, and other factors. Recommended methods for testing corrosion, mechanical properties, and other properties are also available in Ref 17.

Electrochemistry and Basic Corrosion Processes

Corrosion is the result of an electrochemical reaction of a metal with its environment. Chemical dissolution of the surface films does play a role and should not be ignored; however, the principal concern with most forms of corrosion is electrochemical.

Corrosion Reactions. Electrochemical deterioration of the metal occurs as positive metal ions are released from the reaction site (anode) and electrons are made available to flow to a protected site (cathode). The flow of electricity and

material loss during this process obey Faraday's laws, resulting in the release of one equivalent weight of metal ions for every 96,500 C of electricity passed through the electrolytic solution.

The electrochemical reaction cell consists of two conducting and electrically connected electrodes in an electrolytic solution. The two electrodes can be dissimilar metals, or they can result from different surface areas of the same metal, defects, impurities, precipitate phases, concentration differences of gas, solution or metal ions, or other variables. A schematic of a corrosion cell is shown in Fig. 10, and a representative oxidation (anodic) reaction and some typical reduction (cathodic) reactions are:

$$\text{Metal (Me)} \rightarrow Me^{2+} + 2e^-$$

Anodic reaction (loss of electrons)

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$$
$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$
$$2H^+ + 2e^- \rightarrow H_2$$

Cathodic reactions (consumption of electrons)

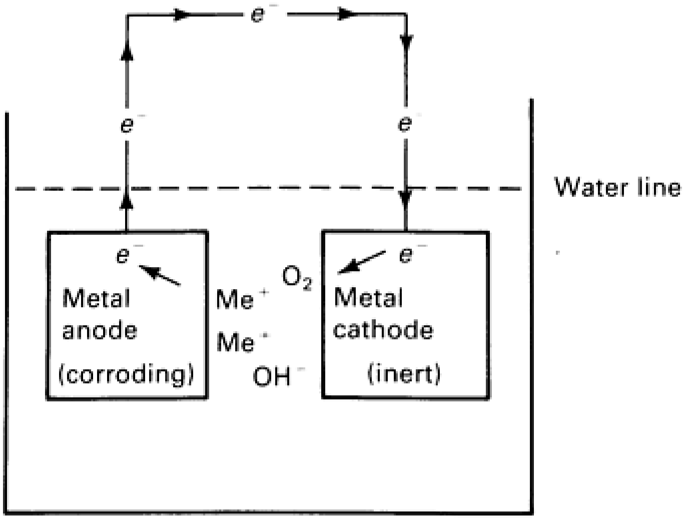

Fig. 10 Schematic of a galvanic-corrosion cell in an aqueous solution

Thermodynamics of Implant Metal Corrosion. Corrosion occurs because the metal oxide or corrosion product is more stable thermodynamically than the metal. There is always a tendency for metals to corrode, with the driving force being the electrode potential difference between the oxidation and reduction reactions. The thermodynamics and kinetics of corrosion of surgical implant metals are discussed in Ref 68, 69, and 70. Corrosion in general is discussed in Ref 68, 69, and 71, 72, 73, and 74. More information on the thermodynamics and kinetics of aqueous corrosion is available in the articles "Kinetics of Aqueous Corrosion" and "Effects of Metallurgical Variables on Aqueous Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook.*

The change in free energy ΔG associated with the electrochemical reaction can be written as:

$$\Delta G = -nFE$$

where n is the number of electrons, F is the Faraday constant (96,500 C), and E is the cell potential. A negative ΔG results in an increased tendency for the electrochemical reaction to occur.

The standard oxidation potentials of metals are measured from a bare metal surface. These potentials can be grouped to indicate active corrosion. This is known as the electromotive force (emf) series (Table 3). The galvanic series (Table 4) is

based on reactions of the material with a specific environment. The galvanic series is more practical than the emf series. Table 4 lists the noble or active tendencies of metals in seawater. In one study, measurements were conducted in equine serum; the values are given in Table 5.

The thermodynamic consideration of the relationship of electrode potential to corrosion is shown in Pourbaix diagrams (Ref 76), in which the electrode potential is plotted versus pH for a given temperature and other conditions (Ref 69). Most of these diagrams predict corrosion behavior for pure metals in water at 25 °C (75 °F). The pH of a solution describes the hydrogen ion (H^+) activity and is equal to -log[H^+]. Although these diagrams are for pure metals, the information is useful for determining passivation and the reactions of alloys. These diagrams serve as a guide for determining corrosion, immunity, or passivity; however, they should be used with care, and the information should be correlated with experimental data when possible.

Figure 11 shows the Pourbaix diagram for titanium. The known areas of immunity, corrosion, and passivity are indicated. Dashed lines a and b refer to the representative equilibrium reactions $H_2 \rightarrow 2H^+ + 2e^-$ and $2H_2O \rightarrow O_2 + 4H^+ + 4e^-$, respectively. The hydrogen pressure at line a is 1 atm, and the oxygen pressure at line b is 1 atm. Oxygen concentrations in solution will be less below line b, and hydrogen concentration in solution will be less below line a.

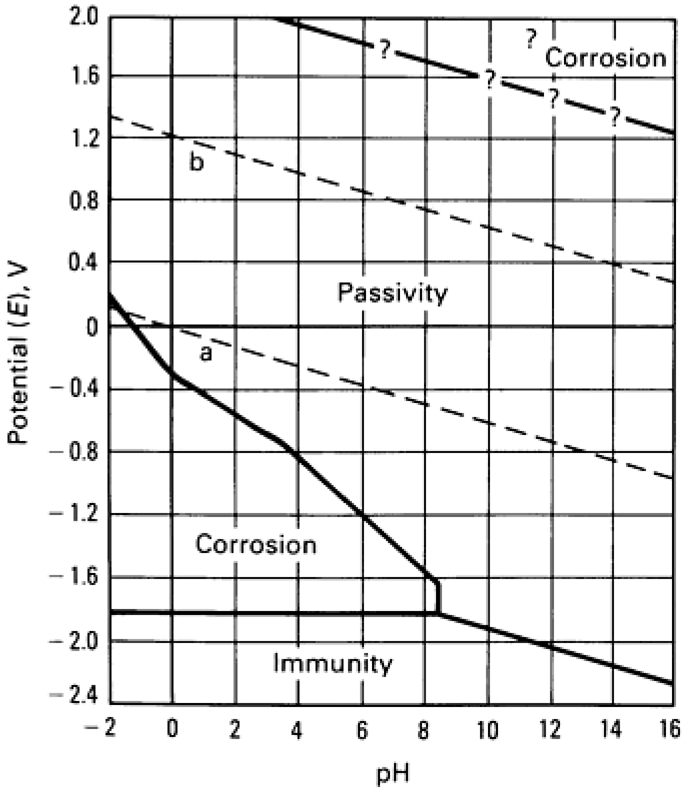

Fig. 11 Pourbaix (potential versus pH) diagram for titanium. Source: Ref 76

Kinetics of Implant Metal Corrosion. The rate at which the corrosion reaction proceeds is related to environmental composition, environmental effects (such as motion or load), and other environmental factors. The rate at which a metal corrodes depends on kinetic factors that are important in determining whether a metal will corrode excessively. For example, there may be a strong driving force or potential difference for a given reaction to proceed, but because of the formation of an impervious surface film or other polarizing action, the reaction rate is slowed or practically stopped. When the polarization occurs mostly at the anode, the system is described as being under anodic control; if the reaction occurs mostly at the cathode, the system is under cathodic control. Figure 12 shows a schematic of an anodic polarization curve for metals that exhibit an active-passive transition.

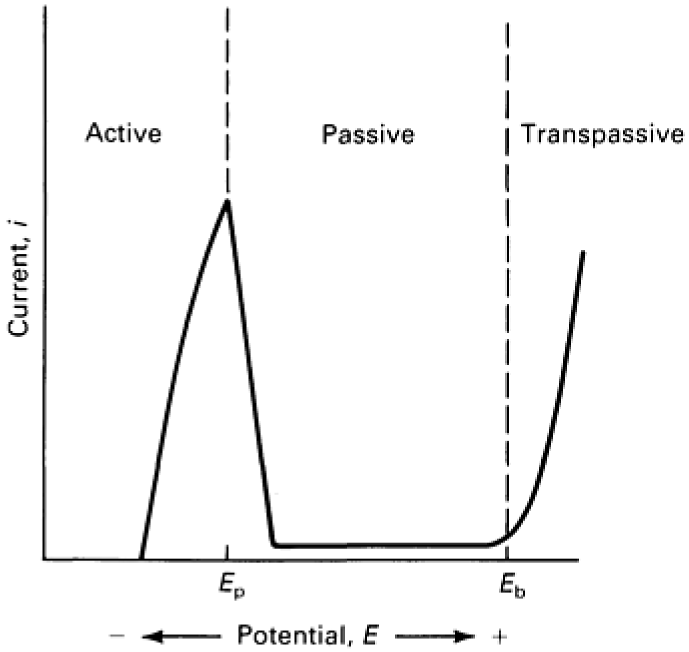

Fig. 12 Schematic of a potentiostatic polarization curve. See text for details

The physiological environment contains chloride ions (Cl^-) and is controlled at a pH level of 7.4 and a temperature of 37 °C (98.6 °F). Following surgery, the pH can increase to 7.8, decrease to 5.5 (Ref 77), then return to 7.4 within a few weeks. Infection or hematoma can cause variations in the pH from 4 to 9. Physiological solutions are oxygenated and contain organic components in addition to the salts. These solutions are electrical conductors.

Surface films on the metals are dominated by certain elements--for example, chromium for the stainless steels and the cobalt-chromium alloys and titanium for the titanium alloys. Changes beyond a specified amount in chromium content of these materials can result in reduced corrosion resistance. Other metallurgical variables can influence corrosion behavior. The corrosion resistance of a material is specific to a number of factors, including composition, changes in metallurgical heat treatment, microstructural phases present, and surface finish.

Forms of Corrosion in Implant Materials

The metals and alloys used as surgical implants achieve passivity by the presence of a protective surface film that inhibits corrosion and keeps current flow and the release of corrosion products at a very low level (Ref 69). The types of corrosion that are pertinent to the alloys currently used are pitting, crevice corrosion, corrosion fatigue, stress-corrosion cracking (SCC), fretting, galvanic corrosion, and intergranular corrosion. More information on all of these types of corrosion is available in the Section "Forms of Corrosion" in this Volume.

Pitting is a severe form of localized corrosion attack that results in extensive damage to the part and in the release of significant amounts of metal ions. Pits may be initiated at breaks in the protective film, defects in the material or protective film, inclusions, voids, and dislocations.

Pit initiation occurs when the protective film is broken by some means and exposes the metal to ions (such as Cl^-), body fluids, and water. Once the pit has initiated, metal ions form precipitates at the top of the pit and often form a film covering the pit. The film restricts entry of the solution and oxygen into the pit, and this makes repassivation, which would renew the protection, impossible. The small area of the pit and pit tip are anodic to the rest of the material, which is cathodic; this results in a high corrosion current density at the base of the pit. Movement of metal ions or H^+ ions from the bottom of the pit is restricted by the film covering the top of the pit. As a result, the pH at the bottom of the pits is lowered to the more acid range, and pitting is accelerated. Figure 13 shows an illustration of a pit and gives selected reactions.

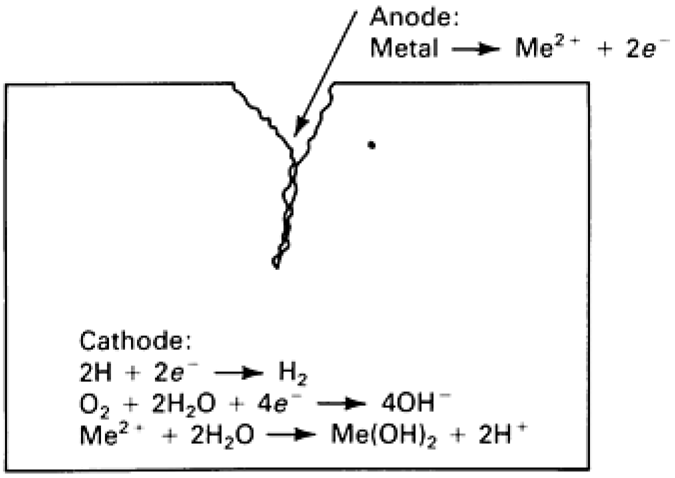

Fig. 13 Schematic of pitting corrosion

Pitting cannot be tolerated in surgical implant metals. The first corrosion test procedure developed by the ASTM F-4/G-1 Joint Committee on Corrosion of Implant Metals was a test to screen passive metals and alloys for resistance to pitting or crevice corrosion (Ref 78). The document specifies an electrode potential stimulation test that is conducted in 0.9% sodium chloride (NaCl) solution at 37 °C (98.6 °F). A Teflon washer is placed on the specimen to create a crevice; therefore, pitting and crevice testing are carried out simultaneously. This test shows that type 316L stainless steel, which was used as a reference material, has a pitting potential of 0 ± 50 mV versus a saturated calomel electrode (SCE). Cobalt-chromium-molybdenum-carbon, titanium, and Ti-6Al-4V do not pit or form crevices in this test, indicating that they are not readily subject to pitting or crevice corrosion.

The importance of assessing pitting corrosion resistance by determining pit propagation rate (PPR) curves is discussed in Ref 79 and 80, which also review the usual tests for pitting. These tests involve anodically polarizing the specimen to a breakdown potential, E_b, at which pitting ensues. If the potential is reversed and in the opposite direction, a protection potential, E_p, is reached below which pits repassivate. If the corrosion potential, E_{corr}, is below E_p, pitting does not occur; if E_{corr} is above E_p, pitting occurs immediately upon immersion. Pitting resistance based on determinations of E_b and E_p have the disadvantage that the value of E_p changes, depending on the amount of pit growth and the length of time of pitting.

The PPR curves are an accurate technique for collecting pitting corrosion data. The PPR data are obtained by applying to the specimen a preselected potential between E_b and E_p and holding at this potential for 10 min. No pitting should have occurred, and the recorded current should be from general corrosion. The applied potential is then increased beyond E_b until a nominal current of 10 mA/cm^2 (64.5 mA/in.^{2}) is reached. The next step is to decrease the applied potential to the same preselected potential and hold there for 10 min. The recorded current is a measure of the rate of general corrosion in the nonpitted areas plus the rate of pit growth. The pits can be repassivated by returning the applied potential to the value of the cathodic potentials, E_c, for 5 min. The process can then be repeated. Some assessment of the pitted area can be made microscopically to determine pit growth area and average pit propagation current densities. This technique can also be used to study crevice corrosion. Application of this method to the study of implant metals is reported in Ref 81.

In one study, hysteresis effects were found upon reversing the applied potential in the polarization scanning when testing passivated cast cobalt-chromium-molybdenum alloy (Ref 82). This normally indicates pitting. However, because no pits were observed on the surface and because the hysteresis effect was not present on the unpassivated material, pitting was ruled out, and the hysteresis in the polarization curves for passivated specimens was attributed to a breakdown of the existing surface film, followed by repassivation. Other cyclic polarization measurements on cobalt-chromium-molybdenum alloy did not show hysteresis (Ref 81).

In another study, potentiodynamic scans were conducted on cobalt-chromium materials; a marked hysteresis was observed with cast cobalt-chromium-molybdenum (Ref 83). It was concluded that the material was subject to crevice attack. However, *in vivo* experiments of cobalt-chromium crevice corrosion test specimens in dogs and monkeys conducted over a period of 2 years found no evidence of crevice corrosion (Ref 84). In addition, accelerated corrosion

tests of the relative corrosion resistance of cobalt-nickel-chromium-molybdenum-titanium and cobalt-chromium-molybdenum alloys showed that the materials have comparable corrosion behavior (Ref 85).

Crevice corrosion is a local attack. It occurs when a metal surface is partially shielded from the environment. Crevice corrosion can occur on metals that would otherwise be resistant to pitting and other corrosion, and it often occurs at a threaded or other type of junction. Damaging ion species accumulate in the crevice, and an environment similar to that of a pit eventually develops. Crevice corrosion problems can often be eliminated by changing the design of a device.

Corrosion fatigue is a fracture of failure of metal that occurs because of the combined interaction of electrochemical reactions and mechanical damage. Corrosion fatigue resistance is an important factor of consideration for load-bearing surgical implant metals or for metals used in cyclic-motion applications. Many corrosion fatigue failures would not occur without the combined, complementary action of these factors. Normally, a failure would not occur, but cracks can initiate from hidden imperfections, surface damage, minute flaws, chemical attack, and other causes. The corrosive environment may result in local corrosive attack that accentuates the effect of the various imperfections. The corrosive attack will be influenced by solution type, solution pH, oxygen content, and temperature.

Stress cycle frequency does not significantly influence the fatigue resistance of materials, and it is convenient and expedient to test at high frequencies. This is not the case for corrosion fatigue. The effects of corrosion depend on the stress cycle frequency, and they increase with decreasing frequency. Frequency is an important factor in the evaluation of corrosion fatigue resistance, and materials should be tested at frequencies identical to those encountered in the use of the material (Ref 67). Figure 14 shows an *S*/*N* curve (stress or applied shear strain amplitude/number of cycles to failure). Corrosion is a dominant process for the material represented by curve B, which does not have a corrosion fatigue limit below which failure would not occur.

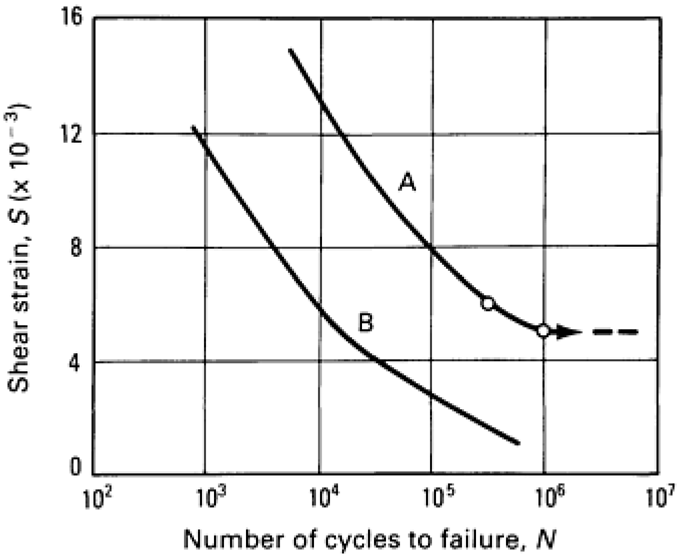

Fig. 14 *S-N* curve. Curve A, the influence of corrosion is small; Curve B, corrosion is occurring.

Fatigue strength measured in aqueous media is usually less than fatigue strength measured in air, as demonstrated in several investigations. In one study, corrosion fatigue tests were conducted on type 316L stainless steel in synthetic physiological solution held at a temperature of 37 °C (98.6 °F) and with a pH of 7.6 ± 0.2 in axial loading with the stress ratio, $R = 0$, at a frequency of 140 Hz (Ref 86). A 10 to 15% decrease in fatigue strength for a given endurance level resulted when testing in the solution instead of in air at 37 °C (98.6 °F) and 25% relative humidity. Fatigue strength was estimated to be 20 to 30% lower when determined at frequency of 1 Hz. Fatigue bending tests were carried out in Ringer's solution (a lactated 0.9% NaCl solution containing about the same concentration of Cl^- ions as body fluids) at a frequency of 1 Hz on type 316L stainless steel and a cobalt-chromium alloy (Ref 87). Results showed a reduction in fatigue strength of both materials when tested in solution:

Alloy	Cycles to failure (40-kg/mm^2, or 57-ksi load)	
	Air	**Ringer's solution**
Type 316L stainless steel	5×10^5	9×10^4

Other studies involving the determination of crack growth rates in Ringer's solution showed that cast cobalt-chromium-molybdenum alloys are susceptible to corrosion fatigue in the human body (Ref 88). Crack growth rates increased, and crack growth threshold levels decreased in solution over the values found for air. Failure was attributed to the synergistic effects of corrosion and cyclic stress, but hydrogen embrittlement was not ruled out. Controlled-potential slow strain rate tests conducted in Ringer's solution demonstrated that cobalt-chromium-molybdenum alloys are susceptible to hydrogen embrittlement (Ref 89).

Alloy Ti-6Al-4V was studied by using reversible torsion corrosion fatigue testing with a selected applied shear strain amplitude at a frequency of 1 Hz in Hanks's physiological solution at 37 °C (98.6 °F) and pH of 7.4 (Ref 90). The results were compared with those obtained in air (Ref 91) and showed only a slight decrease in fatigue strength in the solution. The tests in air were conducted at a frequency of 0.2 Hz and at a higher shear strain amplitude (±0.020 compared to ±0.18 in aqueous solution). These torsion tests conducted on type 316L, cobalt-chromium-molybdenum, and Ti-6Al-4V in Hanks's solution showed Ti-6Al-4V to have superior corrosion fatigue resistance over type 316L and cobalt-chromium-molybdenum.

Previous work found this same ranking of the corrosion fatigue resistance in saline solutions (Ref 92). Another study reported that rotating-bending tests at a frequency of 100 Hz in air gave fatigue strengths of 600 to 660 MPa (87 to 96 ksi) for Ti-6Al-4V, 500 to 800 MPa (73 to 116 ksi) for cobalt-chromium-molybdenum, and 400 to 780 MPa (58 to 113 ksi) for cobalt-nickel-chromium-molybdenum (Ref 93). The wide variation in fatigue strength is due to tests on different material of the same composition that were heat treated or processed in different ways and shows a range of strength available for these materials. A minimum rotating-bending fatigue strength needed for a hip prosthesis was estimated at 400 MPa (58 ksi) (Ref 93).

Stress-corrosion cracking is a form of localized corrosion that occurs when a metal is simultaneously subjected to a tensile stress and a corroding medium (Ref 94). A single mechanism to explain the process of SCC has not been found, but several mechanisms have been shown to be important in this complex interaction of electrochemical, mechanical, and material factors. One mechanism is the occurrence of preferred anodic dissolution at the crack tip due to high plastic deformation, which causes rupture of the protective film. Another mechanism involves the adsorption of ion species at strained areas in the crack tip, and this results in weak bonds within the metal and the film. In other cases, cracking appears to propagate as a series of brittle fracture events.

Stress corrosion differs from corrosion fatigue in mode of cracking and in the application of the stress. Stress-corrosion cracks are often branched, but fatigue cracks follow a more direct path with some striations and other microstructural effects. The loading in SCC is static, but the loading in corrosion fatigue is cyclic. Hydrogen embrittlement failure also results from static stress, but in this mechanism of failure, the adsorption of hydrogen and the production of a brittle region at the crack tip are required. Hydrogen can be produced from cathodic reactions. As a result, cathodic protection, which can be used to prevent SCC, cannot be used to stop hydrogen embrittlement.

Stress-corrosion cracking, corrosion fatigue, and hydrogen embrittlement failures can be impeded by a number of methods. The first is to select a material that is not susceptible to this type of failure in the body. Other methods of increasing immunity are to shot peen the surface to produce compressive stresses, to remove surface flaws that could act as crack initiation sites, and to heat treat the material to produce optimum microstructures for resisting mechanical damage.

Fretting occurs when two surfaces are in contact and experience small-amplitude relative oscillatory motion. Fretting corrosion involves wear and corrosion, in which particles removed from the surface form oxides that are abrasive and increase the wear rate. In some cases, the wear debris may be soluble, and increased wear would not occur. Instead, chemical reactions would play a larger role in the deterioration of the material.

Fretting corrosion can have significance for metallic surgical implants because it offers mechanisms of metal ion release in the body and of mechanical failure. Fretting destroys the passive film by which the implant metal achieves its corrosion resistance. Fretting corrosion is extensively discussed and is related to many applications in Ref 95. Fretting corrosion has occurred with plate and screw portions of prosthetic devices, and it could be the cause of fatigue fractures of these appliances (Ref 96). Reference 97 details a test method for measuring fretting corrosion of osteosynthesis plates and screws, and a test method is being developed for measuring fretting corrosion of surgical implant metals.

Galvanic corrosion is different from the various forms of corrosion discussed. It concerns the reactions of dissimilar metals. The electrochemical reaction that results when two dissimilar metals are in contact depends on the difference in potential of the two metals; the less noble metal becomes the anode, and the other the cathode. Table 5 (galvanic series) lists the corrosion potentials of implant metals. This information on the corrosion tendency, coupled with measurements of the corrosion rate and other factors, can help predict reactions of these metals in physiological use. The area ratio of the anode to cathode must be taken into account when making this assessment of corrosion behavior. A large anode coupled to a small cathode could produce a low current density, which would indicate a low corrosion rate. The opposite conclusion could be made if the sizes of the anode and cathode were reversed.

The corrosion behavior of coupled metals is discussed in Ref 98, and corrosion tests of coupled metals are reported in Ref 99. These discussions indicate that in some cases coupled metals can be used for surgical implants. It is possible for the couple to result in enhanced protection; this is the case for titanium with platinum in acid solutions (Ref 67, 69), in which the platinum in the couple causes the potential to be in the passive region of the polarization curve and not active as it was for titanium alone. Expert knowledge of corrosion principles and corrosion testing is required to determine the suitability of coupled metals for surgical implants. If this expertise is not available or if there are any uncertainties, it is best to avoid the use of coupled dissimilar metals.

Intergranular corrosion occurs when the grain boundary becomes anodic or cathodic to the rest of the grain. The change in composition in the grain boundaries may be due to precipitated grain-boundary phases, concentration of impurities, or elemental depletion near the grain-boundary area. The disorder and higher energy of the grain boundaries also provides a means for collecting second phases or contaminating materials that can lead to corrosion.

Corrosion Tests for Evaluating Implant Metals

The experimental apparatus for conducting corrosion measurements can be as simple as that shown in Fig. 15. The components of the apparatus can be altered for making corrosion fatigue, stress corrosion, or other specific measurements. The measurements can be done manually or automatically.

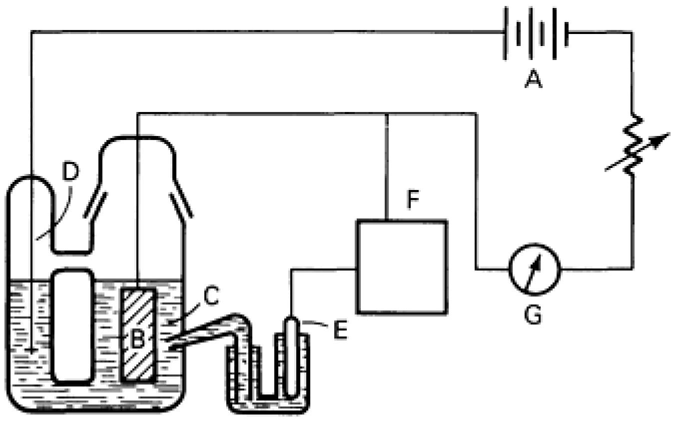

Fig. 15 Schematic of polarization testing apparatus. A, battery or power supply; B, test specimen; C, test environment; D, counter electrode; E, reference electrode; F, high-impedance volt meter; G, ammeter. Source: Ref 69

Corrosion measurements are sensitive to any changes in environment, specimen condition, or electrochemical disturbance. The corrosion process is specific to a given set of conditions. Several factors influence the results of corrosion tests regardless of the type of test being performed:

- Specimens cannot be reused for testing except when the effects of testing can be removed
- Specimens that have been in solution and then exposed to the air should have the surfaces prepared again before testing
- Specimens that are accidentally disturbed electrically during the test will not give a reproducible result
- Surface preparation of the specimen should be kept constant for a given set of experiments; a highly polished surface will be more uniform and will provide a more accurate measure of the surface area
- The specimen surface should be clean and free of all contaminants, including fingerprints
- The pH of the testing solution should be monitored at least before and after the test. Solution pH affects the corrosion processes and the stability of the surface films present
- The oxygen content of the solution should be kept constant by aerating or by deaerating
- The temperature of the solution should be monitored and kept constant
- The reference electrode should be handled with care, kept in good condition, and checked for accuracy. Voltages should be given in reference to an electrode, such as the standard hydrogen electrode (SHE) or the SCE
- All leads should be shielded at the air/solution interface. This is also true for the specimen. It must be totally immersed
- The amount of time between each step in potential and the voltage increment of each step should be kept constant to obtain reproducible results. The time required to reach a reasonably steady current will vary for different metals. It is possible to step the potential too rapidly, and active regions or other variations in the polarization curve would not be recognized
- Caution should be exercised and care taken not to touch any electrical leads in all tests and especially in galvanostatic measurements, because the voltage can produce electric shock. The one-hand rule should be observed, and the power always should be turned off before touching the leads and equipment

Galvanostatic polarization measurements are performed by applying a current and measuring the resulting potential. This technique is used for Tafel curve and linear polarization measurements, and its applications include corrosion rate measurements. Tafel curves and Tafel slopes are determined by applying currents ranging from 1 μA to 10 mA in small uniformly spaced increments and recording the steady-state potential after 2 to 5 min. The Tafel slope is evidenced by the straight line portion of this curve. There may be a deviation at the beginning of the curve due to anodic dissolution and a deviation at the latter part of the curve due to concentration polarization and resistance effects between the Luggin probe and the electrode.

The experimental determination and theoretical implications of galvanostatic polarization measurements are discussed in Ref 69. Figure 16 shows a plot of potential versus log current. These curves are obtained by placing the specimen in an aqueous environment, measuring the open-circuit potential after a designated time, and then applying a current. This open-circuit potential is also the corrosion potential E_{corr}. The anodic curve is determined by applying positive currents in small increments and measuring the resulting potential for each increment. The cathodic curve is established in the same manner by applying small negative-current increments and measuring the resulting potential. The linear portions of the curves can be extrapolated and will intersect at E_{corr}.

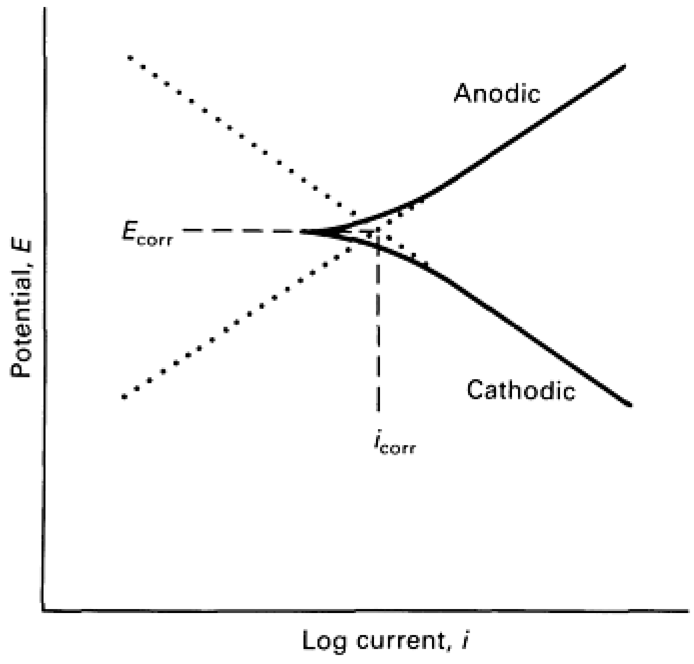

Fig. 16 Schematic of a potential versus log current density curve for anodic and cathodic galvanostatic polarization curves. Source: Ref 69

Further extrapolation of these lines brings them to the potentials for the reversible anodic and cathodic reactions. These reactions determine the signs of the corrosion cell, with the anode being negative and the cathode positive. The extension of the anodic line to the reverse potential brings it to a potential at which the metal is in equilibrium with its ions, and the extension of the cathodic line brings it to the reversible potential for the cathodic reaction. Figure 17 shows plots of these extended lines, known as Evans diagrams.

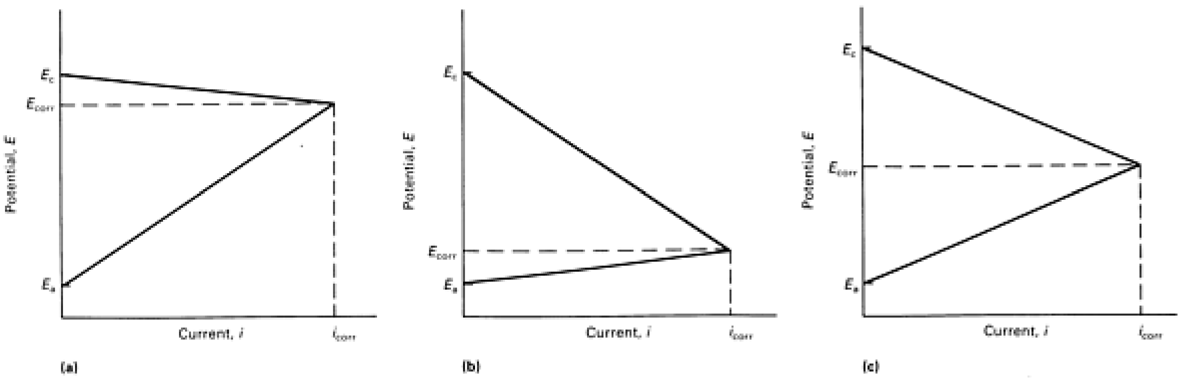

Fig. 17 Evans diagrams showing three types of corrosion rate control. (a) Anodic control (controlled by reactions at the anode). (b) Cathodic control (controlled by reactions at the cathode). (c) Mixed control (controlled by a mixture of both anodic and cathodic reactions). E_{corr}, corrosion potential; E_c, cathodic potential; E_a, anodic potential

Polarization resistance measurements are described in Ref 100, which also includes the derivation of an equation to relate polarization resistance and Tafel slopes to corrosion rate. The Stern-Geary equation has been widely used in the determination of corrosion rates. Galvanostatic polarization resistance measurements are described in Ref 101; these measurements do not disturb the system. The use of an ac impedance technique that superimposes a small amplitude overpotential between the test electrode and the reference electrode is discussed in Ref 102 and 103; this superimposition

causes a phase shift or perturbation in the current. The ac impedance method is also nondestructive to the specimen and uses the Stern-Geary equation to determine corrosion current density.

Potentiostatic anodic polarization measurements are performed by applying a potential and measuring the resulting current. The applied voltage increment should be small. A recommended rate of applying the potential is 0.006 to 0.012 V/min. This technique is especially suitable for measuring the corrosion behavior of active-passive metals, such as those used for surgical implants. These measurements will show the length of the passive region in terms of applied potential, the breakdown potential, and the magnitude of the current in the passive region. The effects of environment, such as solution pH and organic constituents, can be studied with this method. Figure 12 shows a schematic of an anodic polarization curve.

Another application of the anodic polarization technique involves studies of repassivation kinetics (Ref 104, 105, and 106). The term repassivation was coined to describe events occurring after surface film rupture in SCC. Repassivation involves the formation of a protective film over the abraded or clean metal surface. Repassivation measurements are made in a device that is designed to permit abrasion of the specimen, apply a preselected potential, and take a measurement (after removal of the abrader) of the anodic current transient by using an oscilloscope or a computer. Curve fitting or analysis of the current decay versus time can be carried out to provide information on the kinetics of the film formation and the stability of the film formed.

Other Corrosion Tests and Chemical Analysis. The electrochemical techniques described in the polarization measurements can be used to apply or measure electrode potentials and currents in corrosion fatigue, stress corrosion, pitting, and other tests. Chemical analysis of corroding solutions can be made with atomic absorption, and surface analysis can be made with several techniques, include x-ray photoelectron spectroscopy and Auger analysis. Chemical analysis can provide data on the amount of metal ions released, the oxidation state of the ions, and the nature of the surface film on the metal after testing.

Tarnish and Corrosion of Dental Alloys

Herbert J. Mueller, Consultant

Introduction

DENTAL ALLOY DEVICES serve to restore or align lost or misaligned teeth so that normal biting function and aesthetics can prevail. Depending on the application, the particular design can take a number of different forms. The dental specialties of restorative, crown and bridge, prosthodontia, orthodontia, endodontia, implant, pedodontia, periodontia, and geriatric find applications. Alloys are used for direct fillings, crowns, inlays, onlays, bridges, fixed and removable partial dentures, full denture bases, implanted support structures, and wires and brackets for the controlled movement of teeth. In addition to applications calling for cast or wrought alloys, other uses of alloys include soldered assemblies, porcelain fused to metal, and resin bonded to metal restorations.

Dental Alloy Compositions. The compositions of alloys utilized to fulfill the diverse applications germane to dentistry include the following elements: Au, Pd, Pt, Ag, Cu, Co, Cr, Ni, Fe, Mo, W, Ti, Zn, In, Ir, Rh, Sn, Ga, Ru, Si, Mn, Be, B, Al, V, C, Ta, Zr, and others. Figures 1, 2, 3, 4, 5, and 6 show a number of typical restorations and appliances fabricated from alloys containing some of these metals.

Compositions for direct filling restorations usually consist of silver-tin-copper-zinc amalgams. Pure gold in the form of cohesive foil, mat, or powder is used only in very limited applications.

Alloys for all-alloy cast crown and bridge restorations are usually gold-, silver-, or nickel-base compositions, although iron-base and other alloys have also been used. The gold-base alloys contain silver and copper as principal alloying elements, with smaller additions of palladium, platinum, zinc, indium, and other noble metals as grain refiners. The silver-base alloys contain palladium as a major alloying element, with additions of copper, gold, zinc, indium, and grain refiners. The nickel-base alloys are alloyed with chromium, iron, molybdenum, and others.

Alloys for porcelain fused to alloy restorations are gold-, palladium-, nickel-, or cobalt-base compositions. The gold-base alloys are divided into gold-platinum-palladium, gold-palladium-silver, and gold-palladium types. The palladium-base alloys are palladium-silver alloys or palladium-gallium alloys with additions from either copper or cobalt. The nickel- and cobalt-base alloys are alloyed primarily with chromium and with minor additions of molybdenum and other elements. In contrast to alloys for crown and bridge use, alloys fused to porcelain contain low concentrations of oxidizable elements, such as tin; indium; iron; gallium for the noble metal containing alloys; and aluminum, vanadium, and others for the base metal alloys. During the heating cycle, these elements form oxides on the surface of the alloy and combine with the porcelain at the firing temperatures to promote chemical bonding.

Alloys for removable partial dentures are primarily nickel- and cobalt-base compositions and are similar to alloys used for porcelain fused to alloy applications. However, carbon is present in amounts up to 0.3 to 0.4% with the partial denture alloys. Carbon is not added to alloys to be used for porcelain bonding.

Alloys that have found applications for support structures implanted in the lower or upper jaws are composed of cobalt-chromium, nickel-chromium, stainless steel, and titanium and its alloys. Wrought orthodontic wires are composed of stainless steel, cobalt-chromium-nickel, nickel-titanium, and β-titanium alloys. Silver- and gold-alloy solders are used for the joining of components. High-temperature brazing alloys are used for the joining of a number of high fusing temperature alloys. Additional information on noble metals is available in the article "Corrosion of the Noble Metals" in this Volume.

Properties. The diversity in available alloys exists so that alloys with specific properties can be used when needed. For example, the mechanical property requirements of alloys used for crown and bridge applications are different from the requirements of alloys used for porcelain fused to alloy restorations. Even though crown and bridge alloys must possess sufficient hardness and rigidity when used in stress-bearing restorations, excessively high strength is a disadvantage for grinding, polishing, and burnishing. Also, excessive wear of the occluding teeth is also likely to occur. Alloys used with porcelain fused to metal restorations are used as substrates for the overlaying porcelain. In this case, the high strength and rigidity of the alloys more closely matches the properties of the porcelain. Also, a higher sag resistance of the alloy at temperatures used for firing the porcelain means less distortion and less retained residual stresses.

Similarly, alloys used for partial denture and implant applications must possess increased mechanical properties for resistances to failures. However, clasps contained within removable partial denture devices are often fabricated from a more ductile alloy, such as a gold-base alloy, than from cobalt-chromium or nickel-chromium alloys. This ensures that the clasps possess sufficient ductility for adjustments without breakage from brittle fractures.

Other properties required in specific systems include the matching of the thermal expansion coefficients between porcelain and substrate alloy, negligible setting contractions with the direct filling amalgams, and specific modulus to yield strength ratios with orthodontic wires. Due to the use of lower gold content alloys because of the gold price market, alloy color is often a consideration. Lighter and pale-yellow gold alloys, as well as white gold alloys, are currently more prevalent. Tarnish and corrosion of all dental alloy systems have been and will remain of prime importance. Table 1 presents some typical mechanical properties for a number of different alloy systems used in dentistry. Additional information on the compositions, properties, and applications of dental alloys can be found in the section "Classification and Characterization of Dental Alloys" later in this article.

Tarnish and Corrosion Resistance

Dental alloy devices must possess acceptable corrosion resistance because of safety and efficacy. Aesthetics is also a consideration and is discussed in the section "Efficacy" in this article.

Safety

Dental alloys are required to have acceptable corrosion resistance so that biocompatibility is maintained during the time the metallic components are used (Ref 5, 6, 7). No harmful ions or corrosion products can be generated such that toxicological conditions result. The effects of the dental alloys on the oral environment have the capabilities for producing local, remote, or systematic changes that may be short-term, long-term, or repetitive (sensitization) in nature (Ref 8). Dental alloy-oral environment interactions have the potential for generating such conditions as metallic taste, discoloration of teeth, galvanic pain, oral lesions, cariogenesis, allergic hypersensitive, dermatitis and stomatitis, endodontic failures, dental implant rejection, tumorgenisis, and carcinogenisis. Figure 7 shows a schematic of useful dental anatomy.

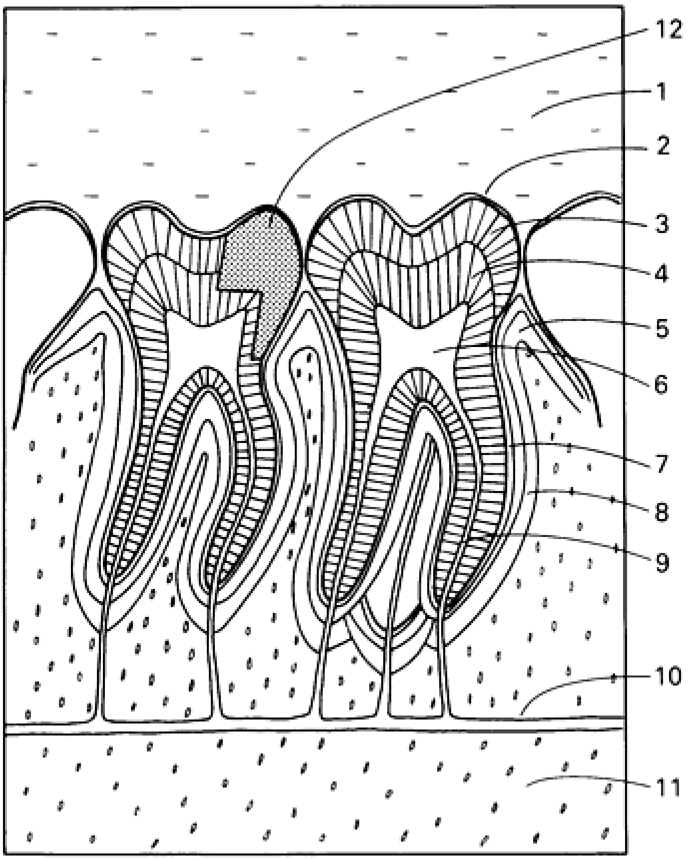

Fig. 7 Useful dental anatomy. 1, saliva; 2, integument; 3, enamel; 4, dentin; 5, gingiva; 6, pulp; 7, cementum; 8, periodontal ligament; 9, root canal; 10, artery; 11, alveolar bone; 12, restoration--amalgam filling

Metallic Taste. The symptom of metallic taste has been reported and related to the presence of metallic materials in the mouth (Ref 9). In addition, the released of ions and the formation of products through corrosion, wear and abrasion can occur simultaneously, which can accelerate the process. Therefore, patients with metallic restorations and with an inclination toward bruxism (the unconscious gritting or grinding of the teeth) are likely to be more susceptible to metallic taste. Although this condition is not as prevalent as it once was when metallic materials with lower corrosion resistances were more often used, metallic taste is still known to occur on occasion.

Discoloration of teeth has occurred mainly with amalgam fillings (Ref 10) and with base alloy screwposts (Ref 11). With amalgams, tin and zinc concentrations have been identified in the dentinal tubules of the discolored areas, while with the screwposts, copper and zinc were detached in both the dentin and enamel and the surrounding soft connective tissue. Discoloration is not, however, a definite indicator of the presence of metallic ions.

Galvanic pain results from contacting dissimilar-alloy restorations either continuously or intermittently (Ref 9, 12). An electrochemical circuit occurring between the two dissimilar-alloy restorations is short circuited by the contact. An instantaneous current flows through the external circuit, which is the oral tissues. The placement of dissimilar-alloy restorations in direct contact is ill advised.

Oral lesions resulting from the metallic prosthesis contacting tissue can be due to physical factors alone (Ref 9). An irritation in the opposing tissues of the oral mucosa can be generated because of the shape and location in the mouth of the prosthesis, as well as its metallurgical properties such as surface finish, grain size, and microstructural features. Tarnish and corrosion can change the nature of the alloy surface and be more of an irritant to the opposing tissues. Microgalvanic currents due to chemical differences of microstructural constituents and due to crevices, such as those created by the partial coverage of the alloy surface by the opposing tissues, must also be considered as possible causative factors in traumatizing and damaging tissue. However, no data have related *in vivo* galvanic currents from dental restorations to tissue damage. The released metallic ions from corrosion reactions can interact with the oral tissues to

generate redness, swelling, and infection. Oral lesions can then occur. These reactions are discussed in the section "Allergic Hypersensitive Reactions" in this article.

Cariogenesis corresponds to the ability for released metallic ions and formed corrosion products to affect the resistance of either dentin or enamel to decay (caries). The mechanisms involved with caries formation (Ref 13, 14), which include the fermentation of carbohydrate by microorganisms and with the production of acid, are likely to become altered when metallic ions and products from corrosion reactions are included. This may be indicated by the reports that show tin and zinc concentrations originating from amalgam corrosion in softened, demineralized dentin and enamel (Ref 15, 16, 17).

Allergic Hypersensitive Reactions. With allergic hypersensitive contact reactions, some people can become sensitized to particular foreign substances, such as ions or products from the corrosion of dental alloys (Ref 9, 18). The metallic ions or products combine with proteins in the skin or mucosa to form complete antigens. Upon first exposure to the foreign substance by the oral mucosa, sensitization of the host may occur in times of up to several weeks and with no adverse reactions. Thereafter, any new exposures to the foreign substance will lead to biological reactions, such as swelling, redness, burning sensation, vesiculation, ulceration, and necrosis. Abstinence from the foreign substance leads to healing. Identification and avoidance are the means for controlling these allergic hypersensitive reactions. Exposure of the oral mucosa to the foreign substance can lead not only to allergic stomatitis reactions (of the oral mucosa) but also to allergic dermatitis reactions (of the skin) at sites well away from the contact site with the oral mucosa. Because the oral mucosa is more resistant to allergic reactions than the skin, the reverse process usually does not occur.

Of the currently used metals contained in dental alloys, nickel, cobalt, chromium, mercury, beryllium, and cadmium need to be considered as inducing possible allergic or cytotoxic reactions. Nickel is the primary alloying element in nickel-chromium casting alloys (up to 80%), in nickel-titanium wires (up to 50%) and in lower concentrations in some cobalt-chromium alloys, and in austenitic stainless steels. Nickel from dental alloy is known to react with the oral tissues in some individuals to produce allergic sensitization reactions (Ref 19). About 9% of women and 1% of men are estimated to be allergic to nickel. It is recommended that individuals be screened for possible nickel allergies prior to dental treatments. If an allergy arises from a dental restoration, it is recommended that the individual be tested for allergies to nickel and have the nickel containing prosthesis replaced with a nickel-free alloy, if so indicated by the testing results.

Cobalt, also a component of some dental alloys, has been known to react with the oral mucosa and cause allergic reactions (Ref 19). However, the occurrences of such allergies are less than 1% of the population and mainly affect women. Testing for cobalt allergies should be performed if reactions to cobalt from cobalt-containing materials are suspected. Contact allergic reactions to chromium from dental alloys are also reported (Ref 19) but the occurrences of such reactions are rate.

Mercury is contained in amalgam filling, which contain microstructural phases composed of silver-mercury and tin-mercury. Mercury ions may be released from microstructural phases through corrosion. However, the concentrations are low and not relatable to toxicological ramifications. Mercury vapors released from amalgam surfaces may also occur. Again, because of the low concentrations emitted, amalgam mercury vapors are not related to toxicity. Allergic reactions to mercury contained in dental amalgams have been reported (Ref 19). If mercury allergic reactions are suspected from the amalgam, it is recommended that testing for mercury allergies be conducted. Mercury vapors pose more of a health risk to dental personnel who routinely handle pure mercury than to individuals having amalgam restorations. Precautions should be followed in handling of pure mercury for amalgams.

Beryllium is contained in some nickel-chromium casting alloys in concentrations up to about 2 wt%. No biological reactions have been related to the beryllium contained in these alloys (Ref 19). More of a health hazard is posed to the dental personnel doing the actual melting and finishing of the alloy than to individuals having a prosthesis made from a beryllium-containing alloy. Precautions for working with beryllium must be followed.

Cadmium is contained in some dental gold and silver solders of up to 15% (Ref 20). No biological reactions have been related to the cadmium contained in these materials. Precautions should be take in fusing solders containing cadmium. Additional information on the biocompatibility of metals and acceptable exposure limits is available in the article "Toxicity of Metal Powders" in *Powder Metallurgy,* Volume 7 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Endodontic Failures. Root canals obturated with silver cones have occasionally been associated with corrosion (Ref 21). Development of a fluid-tight seal at the apex of the root canal is the primary objective of endodontic therapy.

Corrosion of the silver points is known to lead to failure by allowing the penetration of fluids along the silver cone/root canal interface. Figure 8(b) shows a schematic of a tooth with cones.

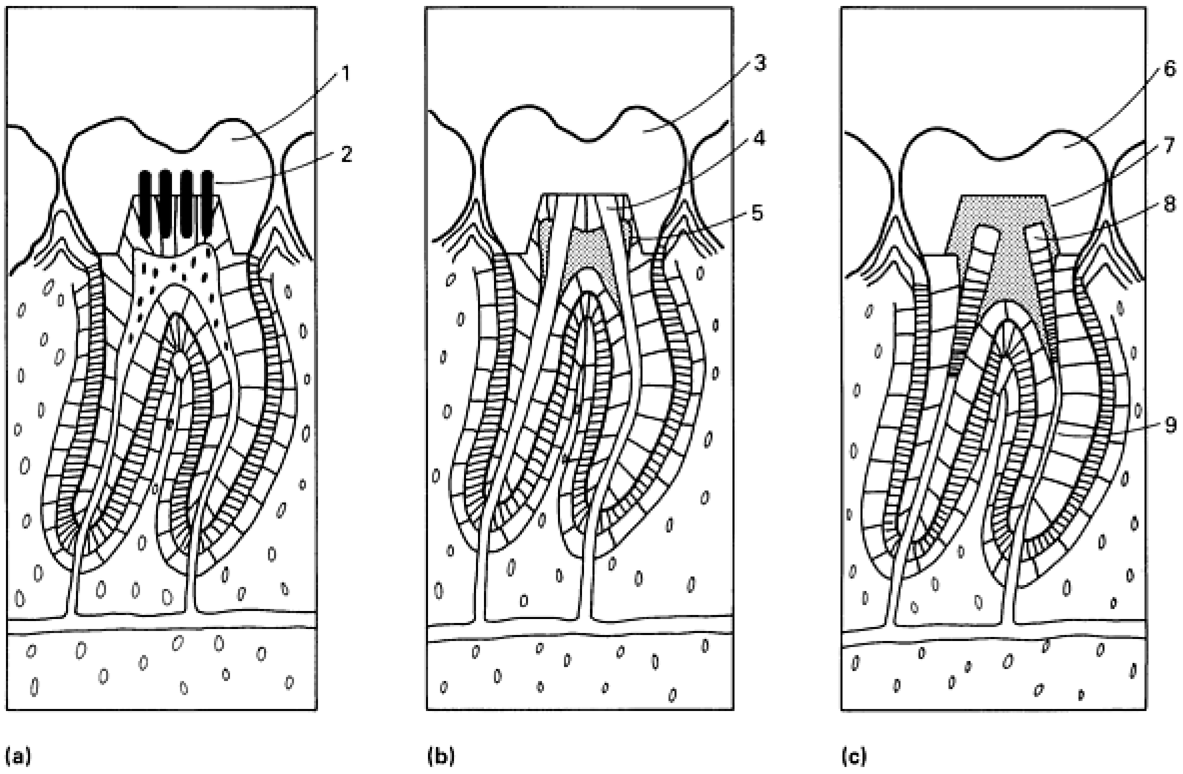

Fig. 8 Typical restored teeth. (a) Pin restored amalgam filling on vital tooth. (b) Cast metal crown restoration on endodontically treated tooth with silver cones and cement to seal root canals. (c) Cast metal crown restoration on endodontically treated tooth with cement core buildup and screwposts. 1, amalgam filling; 2, stainless steel pins; 3, metal crown; 4, silver cones; 5, cement; 6, metal crown; 7, cement core; 8, screw posts; 9, gutta perch or similar sealing material

Dental Implant Rejection. Dental implants, which are used for permanently attaching bridges, and so on, extend through or up to the maxillary or mandibular bones and must function in both hard and soft tissues as well as within a wide range of applied stresses (Ref 22, 23). Depending on the chemical inertness of the materials used for these devices, the thickness of the tissue connecting implant to bone varies. Released ions can infiltrate thick membranes surrounding loosely held implants, which can lead to an early rejection of the implant through immune response.

Tumorgenisis and Carcinogenisis. Even though dental alloy devices have not been implicated with tumorgenisis and carcinogenisis, their possible formation must never be ruled out and should always be considered as potential biological reactions, especially with new, untried alloys (Ref 23).

Efficacy

The oral environment must not induce changes in physical, mechanical, chemical, optical, and other properties of the dental alloy such that inferior functioning and/or aesthetics result. The effect of the oral environment on the alloy has the potential for altering dimensions, weight, stress versus strain behavior, bonding strengths with other alloys and with nonmetals, appearances, and creating or enhancing crevices. In combination with mechanical forces, the oral environment is capable of generating premature failure through stress corrosion and corrosion fatigue and of generating increased surface deterioration by fretting, abrasion, and wear.

Dimensions, Weight, Mechanical Properties, and Crevices. At least in theory, corrosion of precision castings and attachments, which rely on accurate and close tolerance for proper fit and functioning, can alter their dimensions, thus changing the fit and functionality of the restorations. Similarly, corrosion of margins on crowns and other cast restorations

can lead to decreased dimensions and to enhanced crevice conditions. Increased seepage of oral secretions into the crevices created between restoration and tooth, microorganism invasion, generation of acidic conditions, and the operation of differential aeration cells can occur. Under these conditions, the bonding of the restoration to the dentinal walls through the underlying cement is likely to become weakened. In combination with the biting stresses, microcrack formation along the interface is likely to occur; this will cause the penetration of the crevice even further beneath the restoration. Eventually, the loosening of the entire restoration may occur.

With amalgam restorations, however, a slight amount of corrosion on these surfaces adjacent to the cavity walls may actually be beneficial, because corrosion product buildup increases dimensions and adaptability. The crevice between and amalgam and the cavity is reduced in width, which leads to a decreased seepage of fluids. On the other hand, corrosion of the amalgam deteriorates its subsurface structure; this is likely to lead to an increased occurrence of marginal fracture, a known problem with amalgams, through corrosion fatigue mechanisms with stresses generated from biting (Ref 24).

The loss of sufficient substance from any dental alloy through corrosion can lead to a reduction in mechanical strength, thus enhancing failure or reducing rigidity so that unacceptable strains occur. For silver-soldered wires, corrosion of the solder leads to a weakening of the entire joint (Ref 25). Loosening of crowns and bridges because of corrosion-induced fractures of posts and pins is also known to occur (Ref 26), as shown in Fig. 8(a) and 8(c). Still other possibilities include the reduction through corrosion in the bond strengths of metal brackets bonded to teeth, as well as the degradation of porcelain fused to metal restorations because of corrosion.

Appearance. Because of the various optical properties of corrosion products, the appearances of tarnished and corroded surfaces can become unacceptable. A degradation in surface appearance without a loss in the properties of the appliance can be taken to be either acceptable or unacceptable, depending on individual preferences. If, however, the tarnished surface promotes additional consequences, such as the attachment of plaque and bacteria or a greater irritation to opposing tissue, then tarnishing must be deemed unacceptable.

Interstitial Versus Oral Fluid Environments and Artificial Solutions.

In order to select and/or develop dental alloys, an understanding of the environment to which these materials will be exposed is imperative. This section will define and compare interstitial fluid and oral fluid environments. In addition, artificial solutions developed for testing and evaluation of dental materials will also be discussed.

Interstitial Fluid

Applications of metallic materials to oral rehabilitation are confronted with a number of environmental conditions that differentiate most dental uses from other biomedical uses (Ref 27). The one major exception is dental implants, because interstitial fluids (the fluids in direct contact with tissue cells) are encountered by both dental and other types of surgical implants (see, for example, the article "Corrosion of Metallic Implants and Prosthetic Devices" in this Volume). As discussed later in this article, other exceptions occur, because restorations in teeth have their interior surfaces in direct contact with the dentinal and bone fluids, which are more similar to interstitial fluids in composition than to saliva.

Other types of extracellular fluids, such as lymph and blood plasma, contain similar inorganic contents and are also likely to come into contact with dental implants, particularly with plasma during and shortly after surgery. Table 2 presents a composition of blood plasma. The inorganic content is similar to the inorganic content of interstitial and other types of extracellular fluids, while the protein concentration for plasma is higher than for other biofluids. For plasma, the major proteins are albumin, globulins, and fibrinogen. For all extracellular fluids, the inorganic contents are characterized by high sodium (Na) and chloride (Cl^-) and moderate bicarbonate (HCO_3^-) contents. Considerable variations in pH, pO_2, and pCO_2 can occur in the vicinity of an implant. In crevices formed between plates and screws, some extreme values ranging between 5 to 7 in pH, and <8 to 110 and <10 to 300 mm Hg, respectively, have been determined (Ref 28). Similar corrosive conditions are expected regardless of the extracellular fluid, provided the effects of the protein and cellular contents are minimal.

Table 2 Mean blood plasma composition

Compound	mg/100 mL

Source: Ref 27

Tissue cells and other types of cellular matter can also directly contact implant material, with the possibility of intracellular fluid permeating through the cell membrane and effecting corrosion of the alloy. Separation by shearing of biological cells from alloy surfaces almost always generates cohesive failures through the cell instead of adhesive failures along the alloy/cell interface (Ref 29). In these situations, intracellular fluids can gain direct access to the surface of the alloy. In contrast to extracellular fluids, intracellular fluids contain high potassium and organic anion contents. The sodium is replaced by potassium and Cl^- by orthophosphate (HPO_4^{2-}). The effectiveness of intracellular fluids in corroding implant surfaces will be governed by the ability of the larger organic anions to pass through cell membranes, which are usually very restricted. Extracellular fluids are therefore the fluids interacting with the implant in most cases, although the possible effects from intracellular fluids must not be dismissed.

Oral Fluids

Whole mixed saliva is produced by the paratid, submandibular, and sublingual glands, together with the minor accessory glands of the cheeks, lips, tongue, and hard and soft palates from the oral mucosa. Gingival or crevicular fluid is also produced, as well as fluid transport between the hard tissues of the teeth and saliva. The composition of the secretion from each gland is different and varies with flow rate and with the intensity and duration of the stimulus. Saliva composition varies from individual to individual and in the same individual under different circumstances, such as time of day and emotional state.

Although about 1 L of saliva is produced per day in response to stimulation accompanying chewing and eating; for the greater part of the day, the flow rate is at very low levels (0.03 to 0.05 mL/min). During sleep, there is virtually no flow from the major glands. At low flow rates, the concentrations of sodium, Cl^-, and HCO_3^- are reduced notably, the concentration of calcium is elevated slightly; and the concentrations of magnesium, phosphate (PO_4^{3-}), and urea are elevated decidedly when compared with stimulated flow rates (Ref 30). It is therefore impossible to define specific compositions and concentrations that are universally applicable. However, compilations of data encompassing large statistical populations have been made by a number of researchers. One typical analysis for the composition of human saliva that utilized the results from many investigators is shown in Table 3.

Table 3 Mean saliva composition

Compound	mg/100 mL
Inorganic	
Na^+	30
K^+	78
Ca^{2+}	6
Mg^{2+}	1
Cl^-	53
HCO_3^-	31
PO_4^{3-}	48
SCN^-	15
Nonprotein organic	
Urea	4
Uric acid	5
Amino acids	4
Citrate & lactate	5
Ammonia	0.6
Sugars	4
Carbohydrates	73
Lipids	2
Protein	
Glycoproteins	45
Amylase	42
Lysozyme	14
Albumin	2
Gamma-globulin	5

Source: Ref 30, 31

The inorganic ions readily detectable in saliva are Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, PO_4^{3-}, HCO_3^-, thiocyanate (SCN^-), and sulfate (SO_4^-). Minute traces of F^-, I^-, Br^-, Fe^{2+}, Sn^{2+}, and nitrite (NO_2^-) are also found, and on occasion, Zn^{2+}, Pb^{2+}, Cu^{2+}, and Cr^{3+} are found in trace quantities. Figure 9 shows the Cl^- and HCO_3^- variations in concentration as saliva is stimulated to flow at a rate of 1.5 mL/min. The O_2 and N_2 contents of saliva are 0.18 to 0.25 and 0.9 vol%, respectively. The carbon dioxide (CO_2) content varies greatly with flow rate, being about 20 vol% when unstimulated and up to about 150 vol% when vigorously stimulated. The buffering capacity is chiefly due to CO_2/HCO_3 system, with that of the PO_4^{3-} system only having a small, limited part. The redox potential of saliva indicates it to possess reducing properties, which is likely due to bacteria reductions, carbohydrate split-offs from glycoproteins, and nitrates. The normal pH of unstimulated saliva is in the 6 to 7 range and increases with flow rate.

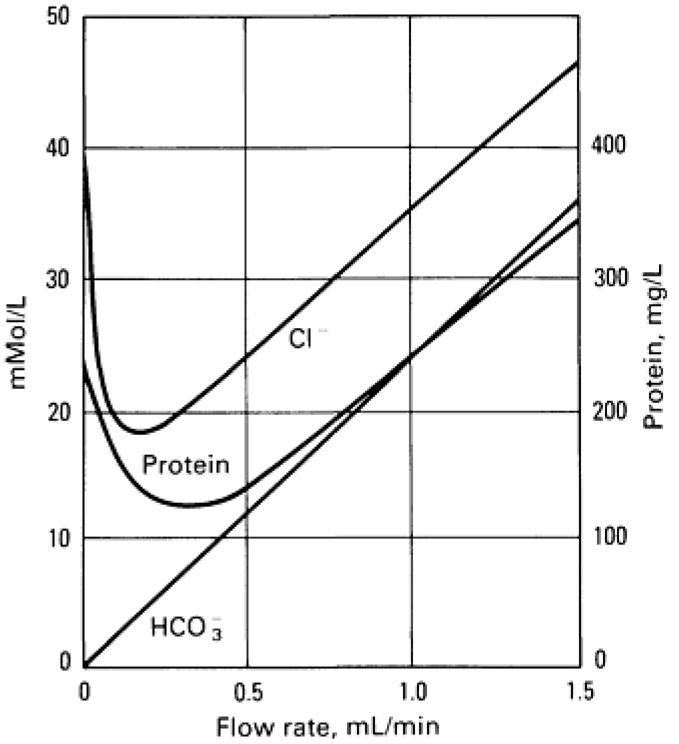

Fig. 9 Variations in the concentrations of Cl^-, HCO_3^-, and protein in human saliva as a function of the flow rate of saliva. Source: Ref 30

The clearance of saliva involves its movement toward the back of the mouth and its eventual introduction into the stomach. Saliva is continually being secreted and replenished, especially during active times. A volume of about 1 L/d is considered average for saliva production. Chemical analysis of human mouth air showed hydrogen sulfide (H_2S), methyl mercaptan, and dimethyl sulfide to be some of the most important constituents (Ref 30).

Organic. Human saliva is composed of nonprotein organic and protein contents, as shown in Table 3. The largest contributions from the nonprotein ingredients are from the carbohydrates, while smaller amounts are from urea, organic acids, amino acids, ammonia, sugars, lipids, blood group substances, water-soluble vitamins, and others. Some of the lipids include the fatty acids, glycerides, and cholesterol. At least eighteen amino acids have been identified, with glycine being the main constituent. Many of these species are produced directly by the salivary glands, while others, such as some carbohydrates and amino acids, are the result of the dissociations of glycoproteins and proteins by bacterial enzymes. Still others are derived from blood plasma. The protein content of human saliva is primarily of salivary gland origin, with a very small amount derived from blood plasma. The protein content may vary from less than 1 to more than 6 g/L. Detailed information on protein and glycoproteins that have been identified to be in saliva can be found in Ref 32, 33, 34.

Chemicals in food, drink, and atmospheric air. All of the ingredients found in food and drink are capable of becoming incorporated into saliva. However, most of the foods are injested before the breakdown into basic chemicals occurs. Some foods and beverages, though, contain chemicals that are reactive by themselves without any reductions and may become dissolved in saliva and affect the tarnish and corrosion of metallic materials. Some of these include various organic acids, such as lactic, tartaric, oleic, ascorbic, fumaric, maleic, and succinic, as well as sulfates, chlorides, nitrates, sulfides, acetates, bichromates, formaldehyde, sulfoxylates, urea, and the nutrients themselves of lipids, carbohydrates, proteins, vitamins, and minerals (Ref 35).

The components found in atmospheric air and pollutants, coupled with the human respiratory function, have the potential of exposing the oral environment to additional aggressive chemical species. Some of the species known to be in atmospheric air and pollutants are O_2, CO_2, NO_2, carbon monoxide (CO), sulfur dioxide (SO_2), Cl_2, hydrogen chloride (HCl), hydrogen sulfide (H_2S), ammonia (NH_3), formaldehyde, formic acid, acetic acid, Cl^- salts, ammonium salts of sulphate and nitrate, and dust (Ref 36).

Because the volume of lung ventilation is of the order of 8.5 L/min, the amount of potentially hazardous and corrosive material possibly coming into contact with the oral environment is significant. In approximately 2 h, 1 m^3 of air for a mouth breather will have been used during respiration with the potential uptake of the normal urban SO_2 amount of 0.11 to 2.3 mg. Sulfur dioxide can be involved in many interactions, accelerating the tarnish and corrosion of metals. Hydrogen sulfide is another reactive gas. Ammonium salts are known for lowering of the surface tension of water and salt solutions. Dust particles may vary from organic to inorganic components of the earth's surface to industrial pollutants. The proteins in saliva combine with most of the aggressive external stimuli coming into contact with saliva. Therefore, most of these hazardous species are rendered inactive before they can cause tarnish and corrosion. However, the pathway from the atmosphere to the surfaces of dental alloys are certainly potential sources for introducing corrosive species.

A comparison between interstitial and oral fluids shows differences in both inorganic and organic contents. One important difference is the approximately sevenfold higher Cl^- concentration in interstitial fluid. Even though interstitial fluids do undergo variations in pH and pO_2, especially at the site of the implant, saliva is more susceptible to variations in composition. This comes about because the composition of saliva depends to a large degree on flow rate, which in turn depends on a number of physical and emotional factors. Saliva is also subjected to exposures from chemicals contained in the air, food, drink, pharmaceuticals, as well as temperature variations of 0 to 60 °C (32 to 140 °F) and microbiological involvement with the production of acid and plaque.

The operation of crevice conditions and mechanical-environment interactions are common to both saliva and interstitial fluid. Differential aeration cells and the generation of acidic conditions accompany crevices, while the biting stresses or the stresses generated in surgical implants, such as from walking, can develop creep, fatigue, wear, and abrasion process. Stress-corrosion cracking (SCC) and corrosion fatigue are additional potential mechanisms.

Artificial Solutions. Numerous solutions simulating human saliva have been formulated and used for testing the tarnish and corrosion susceptibility of dental alloys (Ref 37, 38, 39, 40, 41, 42). Modifications to these solutions have also been made and used (Ref 43, 44, 45, 46, 47, 48). Some of the solutions contain only inorganics (Ref 40, 41, 42, 46, 47, 48), while others include the addition of an organic component consisting mostly of mucin (Ref 37, 38, 39, 43, 44, 45). Some solutions also purge a $CO_2/O_2/N_2$ gas mixture through the solution to simulate pH control and buffering capacity controlled by the CO_2/HCO_3^- redox reaction. All compositions contain mostly chlorides (Na, K, and Ca) and various forms (mono-, di-, or tri-basic, pyro) of phosphates in smaller amounts. Additional ingredients include bicarbonate, thiocyanate, sulfide, carbonate, organic acids, citrate, hydroxide, and urea.

Table 4 presents the composition for an artificial saliva that corresponds very well to human saliva with regard to the anodic polarization of dental alloys. Ringer's physiological saline solution used to simulate interstitial fluid is also included in Table 4. Both solutions are entirely inorganic. The Cl^- concentration of Ringer's is about seven times higher than that of the saliva. The anionic content of Ringer's is entirely chloride, but that of saliva also contains phosphate and sulfide. Urea is also a part of the saliva. Sodium, potassium, and calcium constitute the cationic content of both solutions.

Table 4 Composition of artificial solutions

Compound	Composition, mg/100 mL	
	Artificial saliva	**Ringer's solution**
NaCl	40	82-90
KCl	40	2.5-3.5
$CaCl_2 \cdot 2H_2O$	79.5	3.0-3.6
$NaH_2PO_4 \cdot H_2O$	69	. . .
$Na_2S \cdot 9H_2O$	0.5	. . .
Urea	100	. . .

Source: Ref 41, 49

A number of additional artificial physiological solutions, some of which are named Hanks, Tyrod, Locke, and Krebs, appear in the literature and have been used to simulate the interstitial fluids. Basically, these solutions contain small additions of modifying ingredients, such as magnesium chloride, glucose, lactate, amino acids, and organic anions. The Ringer's solution presented in this article, after the National Formulary Designation, does not contain sodium bicarbonate ($NaHCO_3^-$). Some solutions, however, referred to in the literature as Ringer's, do contain bicarbonate.

Effect of Saliva Composition on Alloy Tarnish and Corrosion

Chloride / Orthophosphate / Bicarbonate / Thiocyanate. The interactions of the various salts contained in saliva are complex. The effects from the combined saliva solutions are not simply the additive effects from the isolated individual salts. This synergistic behavior is discussed for the corrosion of an amalgam in the $Cl^-/HPO_4^{2-}/HCO_3^-/SCN^-$ system in Ref 42. Chloride alone produces a powdery, finely crystalline corrosion product in heaps around the sites of attack, such as porosities and pits. The addition of HPO_4^{2-}, which by itself produced very little effect, caused the corrosion products to become organized in conical structures, the bases being over the sites of corrosion. The addition of HCO_3^- to the Cl^-/HPO_4^{2-} system generated increased microstructural corrosion. On the contrary, addition of SCN^- to the Cl^-/HPO_4^{2-} system suppressed the microstructural corrosion. By adding all four salts together, an even more corrosion-resistant system was obtained. Corrosion was much reduced and more localized.

Artificial Salivas. The effect on alloy corrosion from different artificial saliva solutions has been studied (Ref 41). The polarization behavior of a number of dental alloys, including gold-base alloys, nickel-chromium, and cobalt-chromium, in artificial salivas without HCO_3^- and SCN^- but with protein provided the best correlation with the behavior observed with human saliva in both aerated and deaerated conditions. The artificial salivas containing HCO_3^- and SCN^- but no proteins constantly shortened the passivation range of the alloys. The specific contributions from Cl^- and SCN^- shortened the passivation range of the gold-base alloy, but phosphate increased the passivation range of all alloys.

Lowering the pH shifted the amalgam polarization curve to increased currents and potentials, while buffering capacity, which was increased by protein content, influenced corrosion behavior under localized corrosion conditions (Ref 50). In sulfide solution, the polarization curves of amalgams indicated increased corrosion (Ref 39, 51). Dissolved O_2 generated both inhibition and acceleration, as reflected by the formation of anodic films and the consumption of electrons by cathodic depolarization. The particular alloy-environment combination determines whether corrosion is inhibited or accelerated.

Chloride and Organic Content. Anodic polarization of amalgams in human saliva compared to Ringer's solution was shown to be shifted by up to several orders of magnitude to lower currents at constant potentials, depending on the amalgam system (Ref 52). These differences were related to the Cl^- concentration of the solutions. The effect of Cl^- on amalgam polarization is well documented (Ref 47, 53, 54). Pretreatment of gold-base alloys in human saliva prior to galvanic coupling with amalgams in a protein-free artificial saliva reduced the corrosion on some of the amalgams studied (Ref 55). Pretreatment of the amalgams had little effect.

Significant reductions in the weight gains of amalgams stored in artificial saliva with mucin as compared to mucin-free saliva have been reported (Ref 39). Anodic polarization of amalgams in artificial saliva or diluted Ringer's solution with and without additions of mucin or albumin was, however, shown to be very similar (Ref 39, 53). Proteins in artificial saliva on silver-palladium and nickel-chromium alloy polarizations were also reported to have little effect (Ref 50). For a copper-aluminum crown and bridge alloy, anodic polarization differences were detected in an artificial saliva with and without additions of a human salivary dialysate (Ref 56). The total accumulated anodic charge passed from corrosion potentials to +0.3 V versus saturated calomel electrode (SCE) was significantly reduced in protein-containing saliva. Similarly, the polarization resistance of the alloy was more than doubled by progressively adding up to 1.6 mg dialysate/mL to saliva initially free of proteins.

Microorganisms. The tarnishing of dental alloys by three microorganisms likely to be found in the mouth has been reported (Ref 57). Some specificity between the degree of tarnish and the type of microorganism was obtained. A likely tarnishing mechanism was due to the organic acids generated by the fermentation of carbohydrate by the bacteria. The section "Oral Corrosion Processes" in this article discusses in greater detail the effect of microorganisms on accelerating corrosion.

Oral Corrosion Pathways and Electrochemical Properties

The electrochemical properties of dental alloy restorations vary widely. Electrochemical potentials, current pathways, and resistances depend on whether there is no contact, intermittent contact, or continuous contact between alloy restoration. This section will examine the effects of restoration contact on electrochemical parameters and will review concentration cells developed by dental alloy-environment electrochemical reactions.

Noncontacting Alloy Restorations

Isolated. The total liquid environment of a restoration includes, in addition to saliva, fluids contained within the interior of dentin and enamel, which are more like extracellular fluids in composition than saliva. Figure 10 shows a schematic of a likely current path for a single metallic restoration. The current path encompasses a route that includes the restoration, enamel, dentin, membranes such as the periodontal ligament, soft tissues, and saliva (see Fig. 7). The conduction of current through hard tissues, including enamel, dentin, and bone, occurs through the extracellular fluids, which are compositionally similar in all hard and soft tissues. However, the current through these different hard tissues will take pathways of least resistances. For example, the resistance of dentin in a direction parallel to the tubules is about 18 times lower than in a perpendicular direction due to the calcification of the tubule walls. Structural details, including imperfections, orientations, and so on, control the actual resistances for particular hard tissue structures.

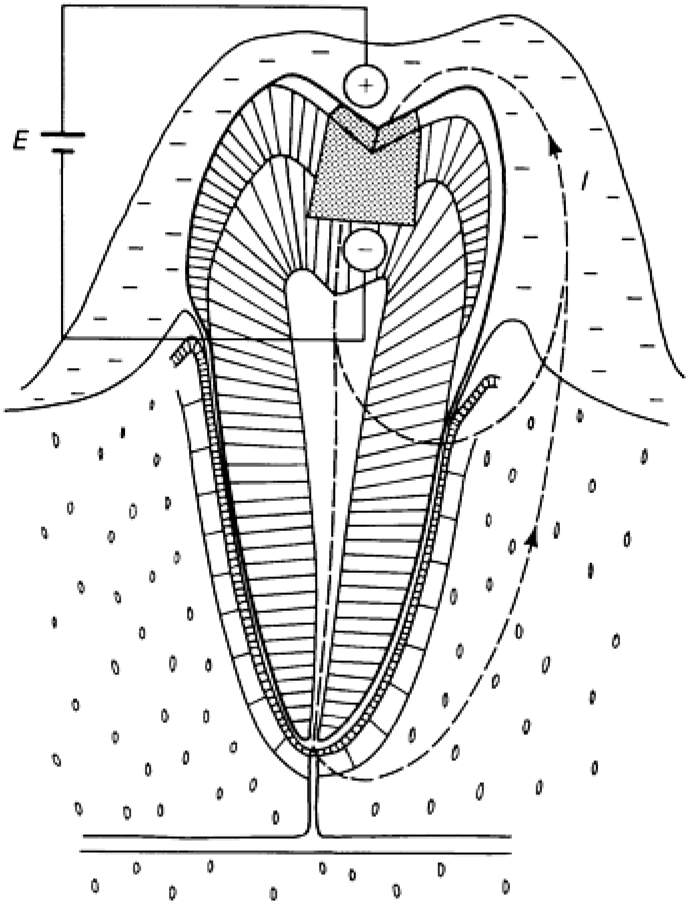

Fig. 10 Schematic of a single metallic restoration showing two possible current (*I*) pathways between external surface exposed to saliva and interior surface exposed to dentinal fluids. Because the dentinal fluids contain a higher Cl^- concentration than saliva, it is assumed the electrode potential of interior surface exposed to dentinal fluids is more active and is therefore given a negative sign (-). The potential difference between the two surfaces is represented by *E*.

The restoration (R) develops electrochemical potentials with the extracellular fluids, E_{RE}, and with saliva E_{RS}, while a liquid junction potential occurs between extracellular fluids and saliva, E_{ES}. Contact resistances occur between restoration and extracellular fluids, R_{RE}, and between restoration and saliva, R_{RS}. Resistances of the extracellular fluids, R_E, extracellular fluid-saliva junction, R_{ES}, and of saliva, R_S, also occur. Figure 11 shows an electrical schematic for this system. Summing electromotive forces (emf) in one direction and equating to zero yields for the current *I*:

$$I = \frac{E_{RE} + E_{ES} - E_{RS}}{R_{RE} + R_{RS} + R_E + R_S + R_{ES}} \quad \textbf{(Eq 1)}$$

Taken together, E_{ES} and R_S have negligible effect on current. The extracellular resistance, R_E is usually in the range between 10^4 and 10^6 Ω because of variations in particular hard tissue structures, and to possible variations in membrane/hard tissue interfacial characteristics. The potentials E_{RE} and E_{RS} are characteristics of the metal-electrolyte combinations, and the resistances R_{RE} and R_{RS} are dependent on the polarization characteristics for the particular combinations.

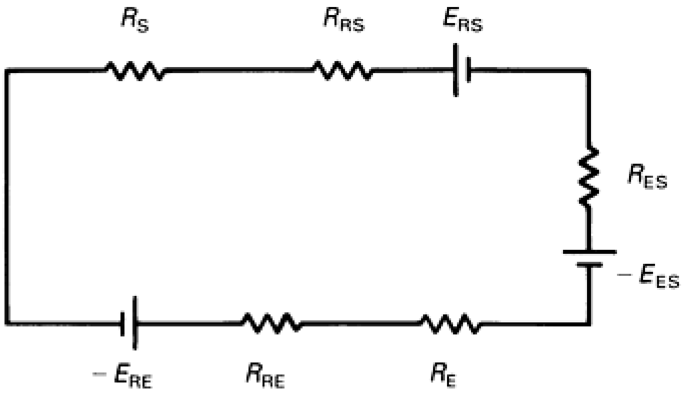

Fig. 11 Electrical schematic representing the equivalent circuit pathway shown in Fig. 10. Terminology is defined in text.

Polarization is related to the corrosion products that form. For soluble or loosely adhered products, the contact resistances will not be changed significantly. However, for tenaciously adhering products with semiconducting or insulating electrical characteristics, the contact resistances will be largely affected. These resistances are the primary parameters affecting the magnitude of the generated current. This reasoning is directly in line with the mixed-potential theory for electrochemical corrosion (Ref 58). The corrosion current, I_{corr}, without ohmic resistance control is:

$$I_{corr} = \frac{\beta_a \beta_c}{(\beta_a + \beta_c) R_p} \qquad \textbf{(Eq 2)}$$

where β_a and β_c are the Tafel slopes from the anodic and cathodic polarization curves, and R_p is the polarization resistance or the linear slope of the $\Delta E/\Delta I$ curve within ±10 mV of the corrosion potential

Nonisolated. For two restorations not in contact (Fig. 12), the extracellular fluid-saliva resistance, R_{ES}, determines the extent to which the current will be short circuited through the saliva/extracellular fluid interface. If R_{ES} is high, there is maximum interaction between the separated restorations (the currents are small, of the order of 1 to 10 × 10^{-9} A/cm^2 between an amalgam and a gold alloy restorations). As R_{RS} decrease, the current through the interface between saliva and extracellular fluids increases. The interaction between the separated restorations will then be minimized. Each restoration, though, will still generate its own current path loop (Ref 59).

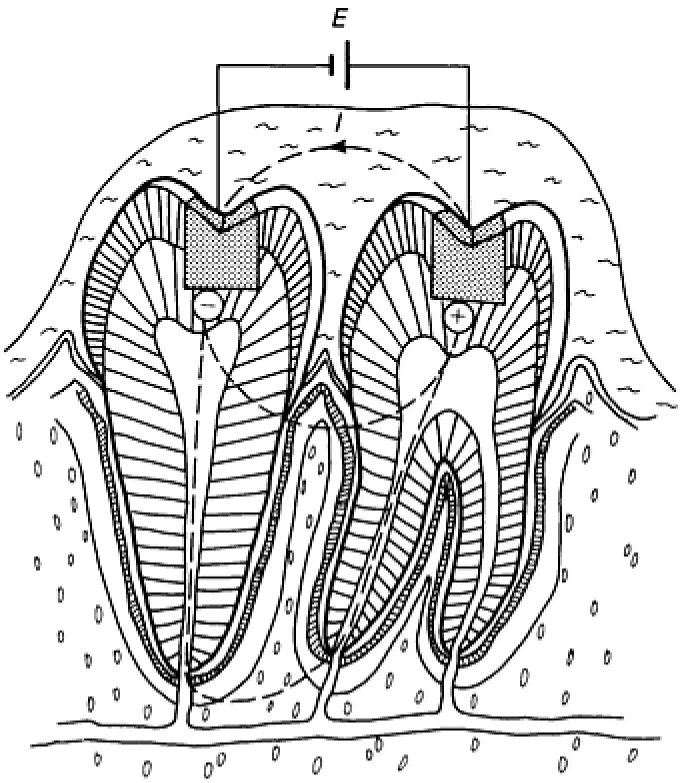

Fig. 12 Schematic of two nonisolated, noncontacting restorations. The alloy restoration on the left, which is an amalgam, is more active than the restoration on right, which is a gold-based alloy

Intraoral Electrochemical Properties. In a study comprising 115 people, the corrosion potentials from 243 restorations ranged between -0.55 and +0.4 V versus SCE. Amalgam restorations were the most active, followed by cobalt-chromium alloys and gold-base alloys. Variations in potential on different surfaces of the same restoration occurred routinely. This was likely due to the effects from abrasion on the occlusal surfaces and from the accumulation of plaque and debris on nonocclusal surfaces (Ref 60).

For noncontacting amalgam and gold alloy restorations (78 fillings in 66 people), the average currents flowing through the restorations due to saliva-bone fluid liquid junction cells were calculated from measured intraoral potential and resistance data to be 0.48 and 0.26 μA, respectively (Ref 12).

Utilizing constant current pulses (1 to 10 μA) and measuring the corresponding potential changes, the intraoral polarization resistances for noncontacting amalgam restorations range between 50 and 300 × 10^3 Ω(Ref 61). With the use of linear polarization theory, corrosion currents are calculated to be 0.2 to 1.0 μA.

Restorations Making Intermittent or Continuous Contact

Intermittent Contact. A situation can occur in the mouth in which two alloy restorations, one in the upper arch and the other in the lower arch, come into contact intermittently by biting (Fig. 13). When the two restorations are in direct contact, a galvanic cell is generated with an associated galvanic current short circuited between the two restorations. The external current path can take a number of directions, with the least resistance path controlling. Figure 13 shows two possible pathways, one entirely through extracellular fluids and the other partly through extracellular fluids and partly through saliva.

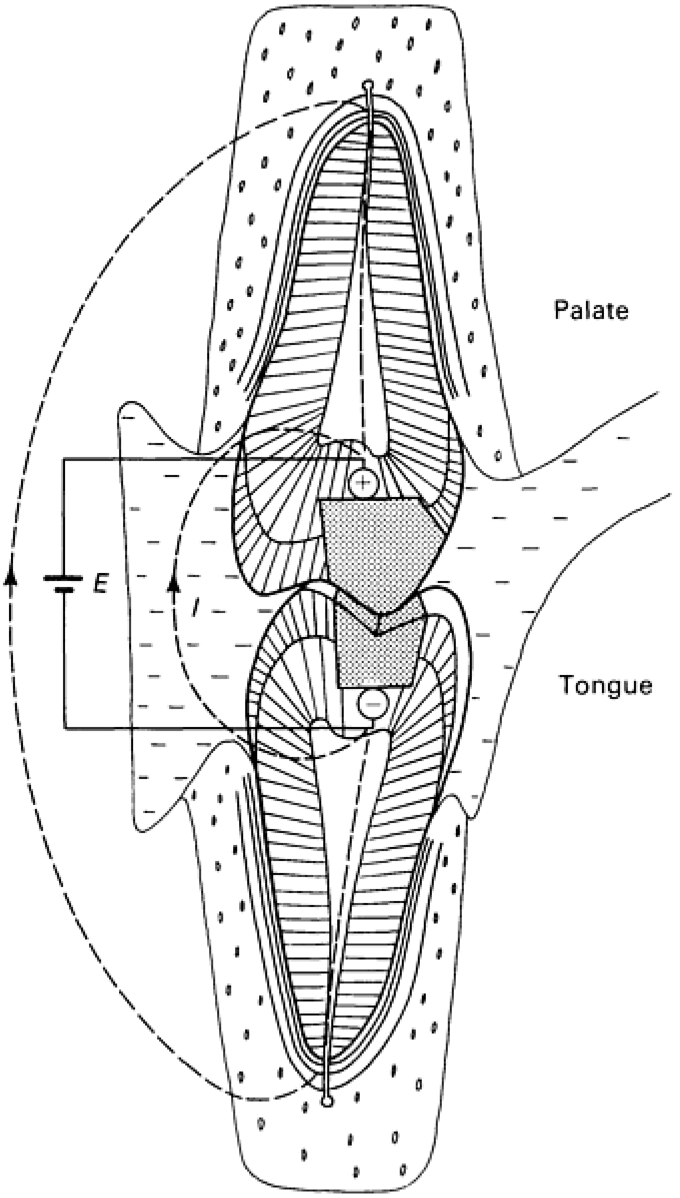

Fig. 13 Schematic of two restorations making intermittent contact due to biting. The restoration in the lower arch, which is an amalgam, is more active than the restoration in the upper arch, which is a gold-based alloy. Two possible current pathways are shown. An additional pathway very likely to occur would be directly through saliva between the two restorations.

The current-time transients have been measured and are presented in Fig. 14. Upon first making contact, currents of the order of 10 μA and more occur and decrease rapidly within a matter of minutes. If, however, the restorations are open circuited for a time interval and then again closed, the current level will again increase but not to the same magnitude as from the previous closure. The amount of recovery will increase as the time lapse between closure increases. This phenomenon is explained by the formation of protective surface films on the electrodes due to the passage of current. Upon making contact on succeeding occasions, the film offers additional resistance to the flow of current, even though the two restorations appear to be in direct intimate contact. The films dissipate with time, thus increasing the level of the initial current upon recontracting restorations.

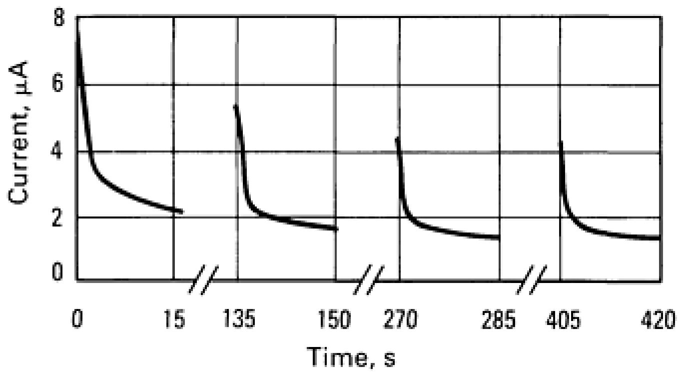

Fig. 14 Current-time responses between gold alloy and amalgam of the same cross-sectional areas. Short circuiting occurred for 15 s, followed by a 2 min delay before recontacting. Source: Ref 62

A similar situation can occur because of an alloy restoration contacting, for example, eating utensils or dental instruments during dental treatment. Again a short-circuited galvanic current is generated. The external circuit will be partly through saliva and partly through extracellular fluids.

Continuous Contact. The fourth situation in which metallic restorations in the mouth are capable of generating galvanic currents involves two dissimilar metallic restorations in continuous contact, as shown in Fig. 15. Most attention has been given to the combination of amalgam-gold alloy couples (Ref 44). Other situations occur, for example, between two amalgam restorations (Ref 63)--one a conventional amalgam and the other a high-copper amalgam--and between two gold alloys with differences in noble metal content. Other situations have already been discussed. These include a stainless steel reinforced amalgam (Fig. 8a), an endodontically restored tooth with silver cones making contact with a gold crown (Fig. 8b), and an endontically restored tooth with steel screwposts making contact with a gold crown (Fig. 8c). Soldered appliances are also examples of dissimilar metals making continuous contact. Any multiphase microstructures are situations for galvanic corrosion to occur. Multiphase microstructures occur extensively with dental alloys.

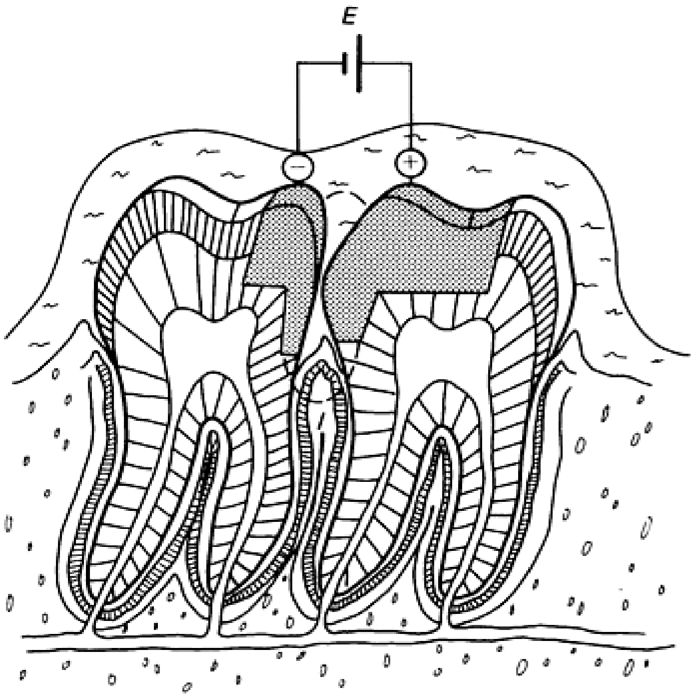

Fig. 15 Schematic of two adjacent restorations in continuous contact. Two possible current pathways shown.

For the amalgam-gold alloy couple making direct contact, the amalgam is the anode and suffers corrosive attack; the gold alloy is the cathode. As with galvanic couples making intermittent contact, large galvanic currents occur upon first contact and decrease rapidly with time. For silver-tin amalgams, the tin from the tin-mercury phase suffers corrosion attack. The freed mercury combines with the gold of the gold alloy to form a gold amalgam that is capable of producing surface discolorations on the gold alloy. In addition to becoming corroded, the amalgam is capable of being degraded in strength by the corrosion generated by the galvanic currents (Ref 63).

Currents calculated from polarization resistance and potential differences of various contacting dissimilar metallic restorations indicate most couples to pass 1 to 5 μA upon first contact (Ref 60). However, amalgam-gold alloy couples indicate a greater percentage of currents in the ranges of 6 to 10 and 11 to 15 μA. All couples initially show a sharp decrease in current with time, followed by a gradual leveling off as zero current is approached. However, disruption of surface protective films is reason for considering possible increases in current at later times.

Concentration Cells

Interior-Exterior Surfaces. Because the interior surfaces of restorations adjacent to the cavity walls are exposed to extracellular fluids and higher concentrations of Cl^- than the exterior surfaces exposed to saliva, the interior instead of the exterior surfaces are more susceptible to anodic attack from Cl^-. However, if the electrons generated by the anodic oxidations are not consumed by reductions, the oxidation reactions will cease. Because the extracellular fluids have low concentrations of dissolved oxygen, corrosion of the interior surfaces would likely cease if it were not for the accessibility of electrons to the exterior surfaces exposed to saliva having a supply of dissolved oxygen from contact with the atmosphere.

Corrosion that is perpetuated by electrochemical reactions occurring on adjacent or opposite surfaces of the same restoration constitutes an important pathway for the tarnishing and corrosion of dental alloys. This pathway is germane to amalgams as well as all types of restorations, including crowns and inlays that are cemented into the cavity preparation. In the mouth, cement are likely to become electrical conductors because the absorption of oral fluids permits the passage of ions.

Marginal Crevices. A second pathway can occur because of the seepage of salivary fluids into crevices or marginal openings formed between the restoration (especially with amalgams) and the cavity walls. The pathway is distinguished from the first in that the conditions developed in the crevice are due to diffusion and charge balances resulting from the salivary fluids instead of the extracellular fluids. Because of a lack of diffusion of the large O_2 molecule into the crevice, low O_2 concentrations result within the crevice. With time, the acidity within the crevice increases because of the accumulation of H^+ ions from the oral environment and from corrosive reactions occurring within the crevice. Chloride and other anion concentrations will also tend to increase within the crevice over time because of charge equalization. Therefore, this pathway results in conditions that are similar to the interior-exterior pathway.

Alloy Surface Characteristics. Porosities, differences in surface finish, pits, weak microstructural phases, and the deposition of organic matter can initiate corrosion by concentration cell effects. For example, gold-base alloys are known to become tarnished more easily when containing porosities and inhomogeneities (Ref 64). Rougher surface finishes of restorations generate increased corrosive conditions (Ref 65). Similarly, the pitting of base metal dental alloys of the stainless steel and nickel-chromium varieties occurs by concentration cell corrosion. Basically, the advancing pit front is free of O_2, but the surfaces of the alloy outside the pit have an ample supply of O_2 from the air. Because the anode-to-cathode surface area is very small, the corrosion occurring at the bottom of the pit is concentrated to a very small area, thus increasing intensity of the attack. Removal of only a small amount of metal has a large effect on advancing the pit front.

Amalgam γ_2 Phase. Deterioration of the weak, corrosion-prone tin-mercury phase (γ-2) in silver-tin amalgams has also been proposed to occur by concentration cell corrosion (Ref 59). In this model, partial removal of the gamma;-2 phase initially occurs by abrasion resulting from biting and chewing. After removal of the γ-2 phase has progressed to a sufficient depth, an occluded cell is formed between the bottom of the depression and the unabraded surface. Mass transport is restricted from and into the cell. The condition will approach conditions occurring in other types of concentration cells. In the present example, however, Sn^{2+} will be slowly released from the passivated γ-2 regions. The concentration of Sn^{2+} will slowly increase within the occluded cell and will be neutralized by an equivalent amount of Cl^- by migration from the bulk electrolyte.

Consumption of O_2 within the occluded cell will take place by its utilization in the consumption of electrons by cathodic depolarization. Replenishment of O_2 will be restricted, and the concentration of O_2 within the cell will become reduced. When the solubility product of stannous oxide (SnO) is exceeded, SnO precipitates and the H^+ concentration increases. At this point, activation of the γ-2 phase occurs. Dissolution of tin occurs freely. The Cl^- concentration within the cell continuously increases to maintain electrical neutrality. Galvanic coupling of the occluded cell to the external surface generates a galvanic cell by which the cathodic reduction of O_2 occurs. Corrosion of γ-2 tin within the cell continues. Under conditions of high acidity and high concentration of Cl^-, the formation of insoluble tin chloride hydroxide ($Sn(OH)Cl{\cdot}H_2O$) becomes thermodynamically possible.

Oral Corrosion Processes

Whether corrosion is occurring between microstructural phases of a single restoration, between components having different environmental concentrations, or between individual restorations of different compositions and making intermittent or continuous contact, the corrosion processes involved consist of oxidation and reduction. The dissolution of ions is involved with the anodic reaction, and the consumption of electrons is involved with the cathodic reaction. The slowest step in the complete chain of events controls the overall corrosion rate. Corrosion of alloys in the mouth can be viewed as being the result of corrosive and inhibiting factors (Ref 66). Some corrosive factors consist of Cl^- (in most instances), H^+, S^- (at times), O_2, microorganisms, and the clearance rate of corrosion products from the mouth, while some inhibiting factors consist of protein and glycoproteins (in most instances), CO_2/HCO_3^- buffering system, PO_4^-/PO_4^{3-} buffering system, and salivary flow rate.

Corrosive Factors

Chloride. The effect of Cl^- on the deterioration of passivated surface films on stainless steel, nickel-chromium, and cobalt-chromium alloys is well known. The susceptibility to pitting attack is increased. Increased Cl^- content also increases the attack of corrosion-prone phases in amalgam, other base metal alloys, and the low noble metal content alloys. Because the Cl^- concentration in saliva is about seven times lower than that in the extracellular fluids, the corrosiveness of Cl^- in saliva is usually less. Figure 16 illustrates the effect of Cl^- concentration on the polarization of amalgam by comparing the cyclic voltammetry in deaerated artificial saliva to that in Ringer's. Increases in Cl^- concentrations are also likely to occur in crevices, such as the interfaces between cavity walls and adjacent surfaces of restoration. The Cl^- concentration within crevices is expected to increase to preserve electrical neutrality from the increase in Sn^+ concentration resulting from the γ-2 tin and γ-1 corrosion (Ref 59).

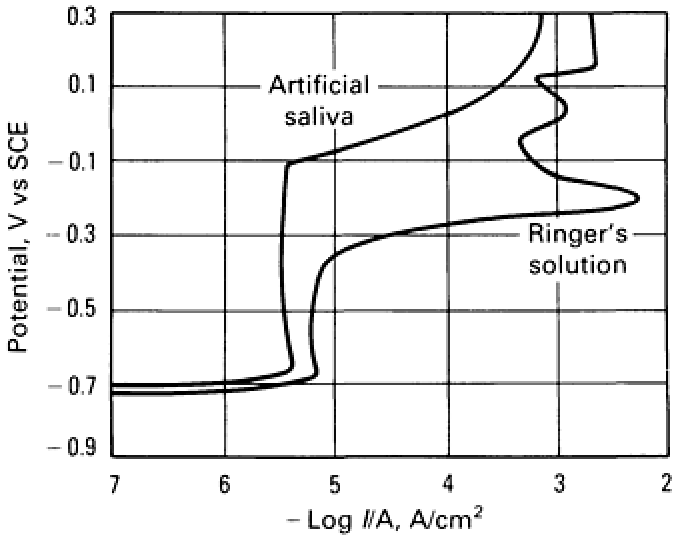

Fig. 16 Anodic polarization at 0.03 V/min of low-copper amalgam (Microalloy) in artificial saliva and Ringer's solution. Source: Ref 67

Chloride is capable of generating numerous compounds as products of corrosion. Chloride combines with zinc, tin, copper, silver, and others contained in dental alloys. Some of the products formed include zinc chloride (ZnCl), stannous chloride ($SnCl_2$), stannic chloride ($SnCl_4$), SnCl compounds such as hydrated $SnOHCl \cdot H_2O$ and $Sn_4(OH)_6Cl_2$, copper chloride (CuCl), cupric chloride ($CuCl_2$), complex hydrated cupric chloride ($CuCl_2 \cdot 3Cu(OH)_2$), and silver chloride (AgCl). The solubilities are high for all compounds, except CuCl, AgCl, and the basic tin and copper chlorides. Many additional compounds are to be considered for a complete listing of all potential corrosion products that form from dental alloys. Certainly, the chlorides of indium, gallium, beryllium, iron, nickel, chromium, cobalt, and molybdenum should be included.

Hydrogen Ion. The pH in the mouth can vary from about 4.5 and lower to about 8. In addition to the normal variations in pH of saliva due to human factors (see the section "Oral Fluids" earlier in this article), increased acidity can also result from a number of additional factors, such as the operation of crevice corrosion conditions, the production of plaque, and the effects of food, drink, and atmospheric conditions. The operation of crevice conditions in amalgams can increase acidity to well below a pH of 4. For amalgams, this acidity is mostly the result of the oxidation of γ-2 and γ-1 tin in aqueous solution. Under these conditions, the freed H^+ will become the cathodic depolarizers. With this increased acidity, dissolution of the tooth structure is also likely to occur. Calcium and phosphorus are likely to be dissolved from enamel and dentin. Plaque is produced by the fermentation of carbohydrate by microorganisms (Ref 13, 14). Most of the fermentable carbohydrate responsible for acid production comes from the diet in the form of sugars or starchy foodstuffs.

Figure 17 shows a schematic Stephan pH test curve of plaque. Stephan showed that the pH for all plaques decrease in value following a sugar challenge (Ref 13). This means that the production of acid by fermentable carbohydrate is greater than the rate at which acid can be removed. As time proceeds, the pH again rises. For caries-free and caries-active individuals, the qualitative shapes of Stephan pH curves are similar; however, the relative position of the curve for caries-active individuals is shifted to lower pH values. Values in pH of 4.5 and lower occur. Depending on the source of the sugar challenge, the pH minimum on the Stephan pH curves have been shown to remain for a number of hours. Even though no data are available to show the effect of plaque pH value on the tarnishing and corrosion of dental alloys, it follows from first principles that the reduction in pH will adversely affect tarnishing and corrosion resistance. Metallic restorations can become severely deposited with plaque and organic matter, as shown in Fig. 18.

Sulfide compounds, such as silver sulfide (Ag_2S), cuprous sulfide (Cu_2S), and cupric sulfide (CuS), have very low solubility product constants and often constitute the tarnished films on dental alloys. Mercury and tin sulfides may also be considered when amalgams are considered. The formation of thin insoluble films occurs with very small amounts of formed corrosion products, especially on the higher noble metal content alloys. In spite of even microgram quantities of tarnishing products at times, surface discolorations can still occur and elicit unsatisfactory personal responses. Tarnishing products under these conditions almost always maintain biocompatibility with the alloy system. With the lower noble metal content alloys, however, increased quantities of corrosion products can form, and tarnishing and corrosion can become more involved.

The corrosion potentials for many dental alloys in sulfide-containing solutions are often lower than the standard reduction potentials for the formation of the metal sulfides--an indication that the metal sulfides are thermodynamically stable. In some instances, particularly with amalgams, dissolution rates increase with S^- concentrations. This is probably due to the increased solubility for some of the sulfides (for example, Sn_2S_3 with amalgams) to form complexes with other species. Dietary factors are the main source for increasing S^- levels in saliva. Some foods, such as eggs and fish, as well as some drinking waters, are high in sulfur. Smokers have higher SCN^- saliva concentrations than nonsmokers (Ref 69). Sulfate-reducing bacteria may also generate S^- in the mouth. Hydrogen sulfide that is produced in the crevicular fluid and periodontal pockets can be easily dissolved in oral fluids. Atmospheric pollutants often contain high levels of SO_2 and H_2S and may influence the concentrations of S^- in the oral fluids.

Dissolved oxygen participates in corrosion reactions by either depolarizing cathodic reactions or by reoxidizing disruptive passivated surface films on base metal alloys. The first case increases or perpetuates corrosion, while the second case reduces or inhibits corrosion. Oxygen depolarization occurs by the customary electrochemical redox reactions. Electrons from the anodic process are consumed by the depolarization process. For a typical restoration, the exterior surfaces are exposed to higher O_2 concentrations. Differential aeration conditions can become operative, with the outer surfaces cathodic to the anodic interior surfaces. In other situations, differential aeration cells are set up between the bottoms of pits and the surrounding surfaces. Other types of pores and porosities are also likely to generate concentration cells. In near-neutral solution that corresponds to saliva, the reaction $O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$ occurs most prevalently. If a driving force exists for metal oxidation, dissolution will be perpetuated on surfaces exposed to the lower O_2 concentration.

Oxygen is involved with numerous corrosion products formed on dental alloys. The tin from the γ-1 and γ-2 phases from silver-tin amalgams generates tin oxide products. These products passivate the amalgam at potentials less negative than about -0.7 V versus SCE, as indicated by the passive regions on the anodic polarization curves shown in Fig. 16. At more noble potentials, basic tin chlorides of the type $SnOHCl\cdot H_2O$ are formed, as indicated by the large current increases on the polarization curves. For copper-containing amalgams, basic copper chlorides of the type $CuCl_2\cdot 3Cu(OH)_2$ form. Some additional products containing oxygen that are likely to occur with the corrosion of dental alloys include SnO_2, $Sn_4(OH)_6Cl_2$, Cu_2O, CuO, ZnO, $Zn(OH)_2$, and the oxides of chromium, nickel, cobalt, molybdenum, iron, titanium, and so on.

Oxygen is usually excluded from solutions during polarization testing with alloys. Dissolved O_2 interferes with the anodic processes. The generated anodic polarization curves obtained in O_2 containing solutions are usually cut off within the negative potential regions. For this reason, deaerated solutions are usually used to obtain entire anodic polarization

curves. Passive breakdown potentials were observed to vary depending upon whether aerated, dearated, or air-exposed solutions were used (Ref 70). Within the O_2 concentration range likely to occur for surgical implants, the anodic polarization of type 316L stainless steel in Ringer's solution was independent of oxygen concentration (Ref 71).

Microorganisms. Two types of organisms--sulfate-reducing (*Bacteriodes corrodens*) and acid-producing (*Streptococcus mutans*) bacteria--have been discussed with the corrosion of dental alloys in the mouth (Ref 66). With regard to sulfate-reducing bacteria, depolarization of cathodic sites is thought to occur by removing H^+ from the metal surface. The hydrogen is utilized by the bacteria for the reduction of sulfate to sulfide, such as by the reaction $SO_4^- + 8H^+ \rightarrow S_2^- + 4H_2O$. In the case of acid-producing bacteria, the adsorbed microorganisms on the surface establish differential aeration conditions. As the dissolution of the metal occurs underneath the deposited microorganisms, the released acidic metabolic products, which include organic acids such as lactic, pyruvic, acetic, proprionic, and butyric, increase corrosion of the already-formed anodic sites. Because anodic areas are relatively small compared to the larger cathodic areas, corrosion can be severe.

The fermentation of carbohydrates by microorganisms generates plaque. The effects of plaque on the tarnishing and corrosion of dental alloys are probably more significant than the effect on alloy corrosion of only the microorganisms themselves. The effects of plaque on corrosion have been considered in the section "Hydrogen Ion" in this article.

Clearance Rate. The clearance of corrosion products from the mouth by the movement of saliva toward the back of the mouth and eventually by swallowing and replenishment affects the concentration of products in equilibrium with the metallic restorations. Therefore, a driving force for the continuation of the corrosion processes is maintained. Products of corrosion, like chemical species introduced through the diet, are cleared from the mouth by binding the exterior surfaces of the oral mucosa to the salivary glycoproteins and mucopolysaccharides lining. Detailed information on the binding ability of corroded metallic ions to proteins in human saliva can be found in Ref 32, 33, and 72.

Alloy Factors. Although the effects of alloy selection on tarnish and corrosion behavior are considered in more detail in the section "Tarnish and Corrosion Under Simulated or Accelerated Conditions" later in this article, some of the important factors will be mentioned here. Alloy composition and microstructure are probably the two most important factors. The corrosion resistance of dental alloys is the result of nobility in composition or the protectiveness of oxide films formed on base metal alloys. Multiphase microstructures are capable of exhibiting increased tarnish and corrosion because of the galvanic coupling of the individual components. The heat treatment state of cast alloys has an important influence on corrosion resistance (Ref 73). Surface state or finish also influence corrosion. Rougher surfaces are more prone to corrosion because of increased tendencies for galvanic coupling. Cast restorations with burnished margins are more susceptible to corrosion because of differences in surface cold-worked states. Rougher surfaces are prone to attachment of microorganisms and plaque, which usually increase corrosion(Ref 74).

Inhibiting Factors

Organics in the form of microorganisms and plaque usually have an accelerating effect on the tarnishing and corrosion of dental alloys (see the sections "Effect of Saliva Composition on Alloy Tarnish" and " Oral Corrosion Processes" earlier in this article). Organics in the form of amino acids, protein, and glycoproteins have received mixed reports. For the amino acids, the building blocks of proteins, the passivation of copper was shown to be improved in Ringer's solution with added cysteine, while nickel became more corrosion prone (Ref 75). Alanine had little effect. For Ti-6Al-4V, the amino acids proline, glycine, tyrosine, and others that constitute many salivary proteins were again shown to have very little effect. For the plasma proteins, which simulate the organic content in blood and which simulate dental and surgical implant applications more closely, additional evidence can be found implicating the effect of proteins on corrosion behavior.

For example, the corrosion rates of cobalt and copper powders increased significantly when exposed to saline solutions with albumin and fibrinogen (Ref 76); however, for chromium and nickel powders only slight increases occured, and for molybdenum, decreases occured. Corrosion of stainless steel by applied external currents was shown to be increased when conducted in saline with added calf's serum (Ref 77). When conducted under fretting corrosion conditions, however, the degradation of stainless steel was shown to increase in saline without the added serum (Ref 78). For a copper-zinc alloy, the cyclic voltammetry was reported to be altered by addition of plasma proteins and plasma concentrations to a phosphated physiological saline solution (Ref 79). Albumin and γ-globulin generated increased passivation currents, while fibrinogen generated decreased critical current densities. The anodic polarizations prior to the onset of critical current densities were also shifted to more active behavior in the protein solutions. Finally, the pitting

potential for aluminum increased slightly in human plasma, and current-time transients were shifted to lower values in plasma (Ref 80).

Carbon Dioxide/Bicarbonate Buffering System. The major buffering system in saliva is the CO_2/HCO_3^- system, which has been found to inhibit corrosion processes on dental alloys. Inhibition results from the deposition of such elements as copper, zinc, and calcium as carbonate films. Carbon dioxide, above all other gases, is contained most abundantly in saliva. Up to about 150 vol% (~3000 ppm) is contained in vigorously stimulated saliva. The equilibrium concentration of HCO_3^- in saliva is identified by the redox reaction:

$$CO_2(g) + H_2O \rightarrow H^+ + HCO_3^- \quad \textbf{(Eq 3)}$$

and with its equilibrium constant pK equal to (Ref 46):

$$pK = 7.9 = -\log \frac{[(H^+)(HCO_3^-)]}{p_{CO_2}} \quad \textbf{(Eq 4)}$$

At a pH = 7 and rearranging terms yields:

$$\frac{p_{CO_2}}{HCO_3^-} = 7.9 \quad \textbf{(Eq 5)}$$

Equation 5 states that the partial pressure, *p*, of CO_2 in units of atmospheres is 7.9 times larger than the HCO_3^- concentration in mol/L. Therefore, for p_{CO_2} of the order of 0.07 atm, HCO_3^- concentrations of the order of 0.009 mol/L are formed. This shows that relatively large concentrations of HCO_3^- can be made available in saliva to form carbonates with cations released from corrosion reactions on dental alloys and with other cations found in the mouth, such as calcium.

Many of the different carbonates likely to form are insoluble in aqueous solution. The calcium carbonates are known for making waters hard. Compounds of this type being deposited as thin-film tarnish and corrosion products on dental alloys are very likely to interfere with the corrosion activity. Deposition over cathodic sites effectively increases corrosion resistance by increasing resistance to depolarization reactions. Because the films of carbonates are also likely to increase the contact resistances between electrodes and saliva, galvanic-corrosion processes are likely to change from purely corrosion control to at least partial ohmic control. Under these conditions, local anodes and cathodes may change in order to maintain lower-resistance paths for both ionic and electronic conduction.The *in vivo* tarnishing of several silver-palladium alloys was shown to be due to the galvanic coupling between microstructural phases located very close to each other on the alloy surface (Ref 81). This was in contrast to laboratory tests in high-conductivity solutions indicating larger distances between microelectrodes.

Phosphate Buffering System. A secondary buffering system in saliva, the PO_4^-/PO_4^{3-} system, has also inhibited the corrosion of dental alloys. The progressive inhibition of chloride (10 millimolar NaCl) amalgam corrosion activity was shown to occur with increasing added phosphate concentrations (Ref 66). A 15 millimolar phosphate addition retarded the anodic polarization almost entirely, while concentrations of 10, 7, 5, and 1 millimolar generated anodic current peaks of about 2.5, 3.0, 3.5, and 6.0 $\mu A/mm^2$, respectively. The 10 millimolar NaCl solution without phosphate generated a continuous increase in current to much larger values. No passivation occurred within the potential range used.

For tin in neutral phosphate solutions, a passive film forms by precipitation or by a nucleation and growth processes (Ref 82). Tin phosphate, basic tin phosphate complexes, and tin hydroxides are formed.

Salivary Flow Rate. Increasing the salivary flow rate increases the concentration of most species in saliva. This tends to inhibit corrosion. The organic content, the CO_2/HCO_3^- content, and the PO_4^-/PO_3^- content, pH, and the Ca^{2+}

content all increases with flow rate. Only the increases in Cl^- concentration promote corrosion. Figure 9 shows the effect of flow rate on the concentration of a number of species.

Overview. Saliva acts as an ocean of anions, cations, nonelectrolytes, amino acids, proteins, carbohydrates, and lipids flowing in waves against and into dental surfaces with a diurnal tide and varying degrees of intensity (Ref 83). Whether or not tarnish and/or corrosion of dental metallic materials will occur cannot be categorically stated. It has been discussed that the degree to which dental alloy corrosion occurs in the mouth is dependent on the oral environmental conditions for each person. In addition to effects from the dental alloy itself, competition between corrosive and inhibitory factors of the oral environment will dictate whether or not corrosion will occur and to what extent. In addition to the factors listed above, still others have been isolated and should be included for a more complete assessment of the overall corrosiveness or protectiveness of the oral environment (Ref 66).

Nature of the Intraoral Surface

The composition and characterization of biofilms, corrosion products, and other debris that deposit on dental material surfaces will be discussed in this section. As will be shown, the nature of these deposits is dependent on the substrate material (enamel, alloy, porcelain, and so on).

Acquired Pellicles

Characteristics. Most surfaces that come into contact with saliva, including enamel and metallic, polymeric, and ceramic dental materials, interact almost instantaneously with the proteins and glycoproteins to form a bacteria-free biofilm of the order of several nanometers in thickness (Ref 84, 85, 86). This most intimate layer of organic matter adsorbed to the substrate material is called the acquired pellicle. A fourier transform infrared spectroscopy (FT-IR) spectra of the surface of a low-gold dental crown and bridge alloy after *in vivo* exposure is shown in Fig. 19. Detection for protein, carbohydrate, and lipid is indicated. (Information on the principles and applications of FT-IR can be found in the article "Infrared Spectroscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*). Thicknesses of the films increase only slightly with longer exposure times. The pellicles, in contrast to enamel and most dental alloys, are acid insoluble, although an acid-soluble fraction also occur. The films are diffusion barriers against acids, thus reducing the acid solubility of enamel and metallic materials and inhibiting or at least reducing the adherence of organisms.

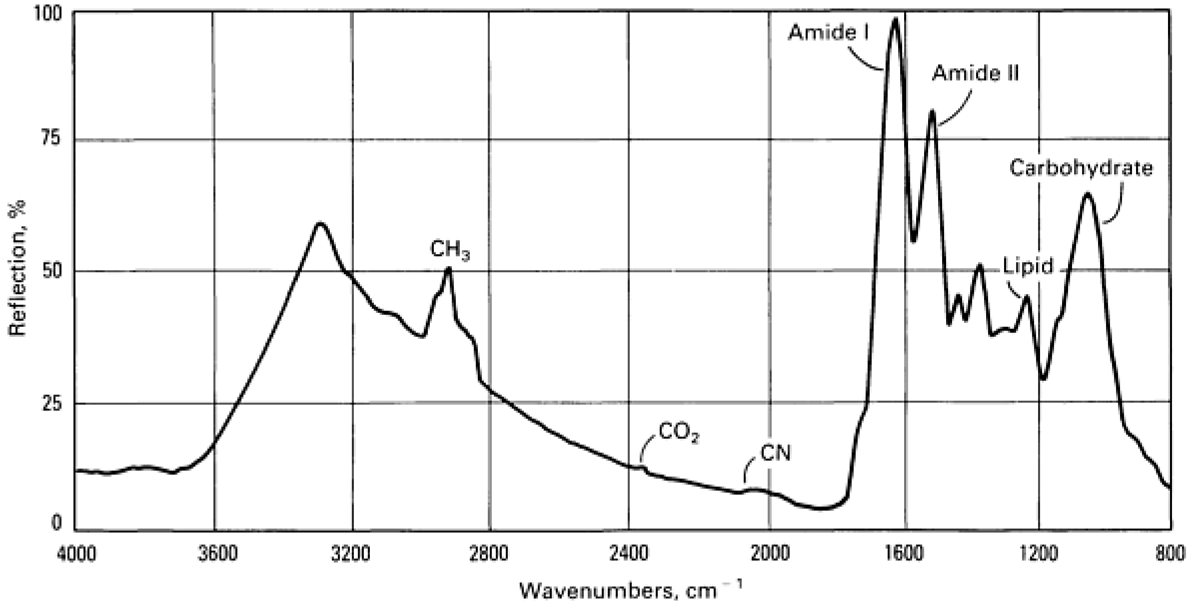

Fig. 19 Fourier transform infrared spectroscopy spectra from surface of a crown and bridge alloy (Midas) after several weeks of intraoral usage. Amide I and II are protein. Additional smaller peaks at 1375 and 1425 cm^{-1} are also protein.

Composition. Chemical analysis of 2-h pellicles formed on enamel indicated abundant amounts of glycine, glutamic acid, and serine (Ref 87). Carbohydrate contents of similar pellicles formed to enamel were found to contain about 70% glucose, with a number of other sugars and small molecules. Acidic proline-rich phosphoproteins have also been identified from *in vivo* enamel pellicles (Ref 88). The proline-rich proteins constitute as much as about 37% of the total proteins in new pellicles within the first hour. However, there is a gradual degradation beginning after about 24 h that is reflected by the fact that the proline-rich protein content in aged pellicles is less than 0.1%.

Substrate Effects on Pellicle Composition. Chemical analysis of the pellicles formed on several plastics and glass showed that the amino acid content varied and was different from that formed on enamel (Ref 89). It was concluded that the chemical composition of the substrate has an important influence on the type of proteins that become adsorbed. For the pellicle formed on dentures, it was concluded that a specific mechanism was controlling the deposition of protein and that specific proteins seemed to be precursors in forming the film (Ref 90). Isoelectric focusing of the extracted proteins adsorbed from a human saliva preparation onto a number of different powder substrate compositions, including palladium, silver, copper, silver-copper, tin, silver-tin-copper alloy, bismuth, polymethyl methacrylate, porcelain, hydroxyapatite, and enamel, indicated that the same three to four proteins appeared to be involved with the adsorption process on all substrates regardless of composition (Ref 33). Therefore, from this study, substrate composition appeared not to affect the type of proteins becoming adsorbed.

Binding Mechanisms. The binding of salivary macromolecules to surfaces has been proposed to consist of electrostatic interactions between the charged groups in the molecule and the surface charges on the substrate (Ref 91). For enamel, only the hydroxyapatite, and not the organic matrix, contributes a surface charge for binding. Because the negatively charged phosphate group comprises about 90% of the surface area of hydroxyapatite, the phosphate group rather than the calcium ions will be the primary binding sites. The hydration layer contains soluble calcium and phosphate ions as well as soluble cations and anions. Because the salivary molecules adsorbed to enamel are mainly acidic, binding to the negatively charged phosphate group appears to occur through a divalent cation, such as calcium. Phosphorylated and sulfated acidic proteins show a high affinity for hydroxyapatite. A direct replacement of the protein phosphate group and the phosphate in hydroxyapatite is also likely (Ref 92).

Direct binding to the calcium surface ions in enamel will also occur, but will be limited because of the relatively small surface area fraction occupied by the calcium ions. Adsorption of salivary proteins to metals may again occur through a divalent cation. The negative charges in the acidic proteins are likely to be bound to the negative anodic surface sites on the metal surface by the bridging cation. Additional information on protein binding and analyses of variations in protein binding to a metal surface through differential scanning calorimetry can be found in Ref 93.

Plaque, Corrosion Products, and Other Debris

Integument. In addition to the thin acquired biofilms, aged pellicles contain microorganisms, plaque, mineralized products, corrosion products, and other debris. Plaque, which is a by product of the reaction between microorganisms and carbohydrates, may form in abundance in some environments. Plaque does not form directly onto teeth or other materials. It is deposited or adsorbed onto the acquired pellicle. The combined surface coating, including the adsorbed pellicle and plaque, which includes organic matter and any released ions or corrosion products generated by the substrate, is often referred to as the integument.

Substrate Effects on Integument Characteristics. A study was made of the effect of the restorative material type on plaque composition (Ref 94). The carbohydrate/nitrogen ratios (CHO/N) were similar for amalgam, gold inlay, gold foil, and resin. Plaque analyzed from freshly placed restorations had CHO/N = 1; this value increased to 1.3 and 1.2 at 3 and 6 months, respectively, and decreased to 0.5 at 1 year and for old restorations. It was proposed that the variation in plaque carbohydrate content with the age of the restoration was due to corrosion or to the absorption of impurities into surface porosities and pits. These mechanisms are supported by the data generated with silicate restorations. This was the only material to show significant differences in CHO/N. The CHO/N was 1.0 at 1 year. This suggests that the carbohydrate is metabolized less efficiently by the silicate. It is known that silicate restorations leach fluoride with time. Therefore, the fluoride acts as an enzyme inhibitor.

The thicknesses of the integuments formed in the mouth vary and may depend on the substrate material. For example, sputtering times in Auger electron spectroscopy depth profiling required only 0.3 min to reach the amalgam substrate, while 2.4 min was required to reach the gold alloy substrate (Ref 86). Carbon, nitrogen, and oxygen were distributed in much the same manner as films formed on different substrates. The main difference between the integuments formed on the amalgam and on the gold alloy was the presence of tin ions with the amalgam and the presence of copper ions with the

gold alloy. The release of substrate ions is likely to interact with the attachment of microorganisms and therefore with the metabolism of plaque.

Substrate Corrosion. Corrosion reactions involve diffusion of ions--whether cations from oxidations or dissolved O_2 and H^+ for reductions--through the formed integument. The surface coating has the ability to act as a diffusion barrier to the movement of ions. Released ions are likely to become complexed, or bound, to the proteins and glycoproteins constituting the integument and free native proteins in the bulk saliva, provided diffusion is not restricted by the integument. Insoluble corrosion products of the oxides, chlorides, sulfides, carbonates, phosphates, and so on, have the capability of being deposited at the alloy/film interface or becoming an integral part of the integument. Soluble products, in addition, may be released into the bulk saliva.

For one dental restorative alloy, it was shown that the polarization resistance of the alloy increased with protein concentration, while at the same time, the concentration of soluble species in solution also increased (Ref 56). This situation was explained by the increased effect of proteins in solubilizing corrosion products. Energy-dispersive spectroscopy (EDS) spectra of the corroded surfaces showed reduced peak intensities for chlorine and sulfur on surfaces exposed to the proteins. Therefore, even though the severity of corrosion is less in protein-containing solutions, increased levels of soluble products are still generated.

***In Vivo* Tarnished Film Compositions.** Auger thin-film analysis of the surfaces of dental alloys with varying compositions and after functioning in the mouth indicated that the tarnished films were due to chemical reactions between alloy and inorganic species and to the adsorption and deposition of organic matter (Ref 35). Carbon was the dominant nonalloying elements by about six times, followed by oxygen, calcium, nitrogen, chlorine, sulfur, magnesium, silicon, phosphorous, aluminum, sodium, and tin. Of the elements from the alloy itself, copper was dominant. In a microprobe analysis of *in vivo* discolorations on gold alloys, both silver sulfides and copper sulfides were detected, depending on the composition of the alloy. Sulfur was found isolated and carbon was present in greatest quantities (Ref 95).

Intraoral (In Vivo) Versus Simulated (In Vitro) Exposures

Need for Laboratory Testing. The tarnish and corrosion behavior of dental alloys under actual oral environmental conditions is required. However, except for selected clinical trials, the initial testing of new and improved alloys for tarnish and corrosion resistance is usually carried out under laboratory conditions in either simulated or accelerated tests. This is so because of:

- The possible human exposure to harmful species
- The variability in the oral environmental conditions from person to person and even with the same person from location to location and with time
- As a result of the variability in the oral environment, the inability to follow the effects on tarnish and corrosion from changes in parameters in alloys and in solution

Most laboratory tests utilize an artificial saliva or a physiological saline solution, such as Ringer's solution (Table 4), diluted Ringer's solution, various concentrations of NaCl, and various concentrations of Na_2S. The main deficiencies with these solutions is that the nonelectrolytes, including the proteins, glyco-proteins, and microorganisms, are not included. This fails to produce the pellicle and integuments on laboratory samples that otherwise would have formed on all intraoral surfaces.

In spite of these shortcomings, for the most part, the inorganic salt solutions have become indicators for the aggressiveness of the oral environment. However, the inability to correlate *in vivo* to *in vitro* behaviors in some instances is likely because of the failure to account for the shortcomings (Ref 81).

The use of solutions with higher-than-normal concentrations accelerates the tarnish and corrosion processes. For example, 3200 immersions of 15 s/min duration in a 5% Na_2S solution with a Tuccillo and Nielsen tarnishing apparatus (Ref 96) is estimated to simulate 12 months of actual in-service use (Ref 97). Ringer's and 1% NaCl solutions, which contain about seven times the Cl^- concentration of human saliva, are used in anodic polarization tests to amplify peaks in current behavior (Ref 53, 54). Corrosion of conventional amalgams in Ringer's or 1% NaCl generates products that are morphologically similar to those from retrieved amalgams after intraoral use (Ref 98, 99).

A comparison of the tarnishing of three gold alloys, both *in vivo* and *in vitro*, indicated that the cyclic immersions in a 5%Na_2S-air environment predicted with considerable reliability the relative susceptibility for the alloys to tarnish (Ref 100). The tarnishing of 81 gold-silver-palladium alloys also indicated accelerated laboratory exposures in Na_2S solution simulated *in vivo* use (Ref 101). *In vivo* and *in vitro* (Na_2S solutions) tarnishing of gold alloys in Na_2S solutions has shown the same microstructural constituents to be attacked (Ref 102, 103). Silver-and copper-rich lamellae were the constituents exhibiting sulfide deposits. Utilizing linear polarization, good agreement with calculated current densities was obtained between measurements whether performed *in vivo* (baboons) or *in vitro* with artificial saliva for times up to 45 days (Ref 104). Differences that occured between *in vivo* and *in vitro* (0.1%NaCl) tarnish measurements as determined by colorimetry were attributed to the effects of abrasion and buildup of plague that occurs on *in vivo* surfaces (Ref 105). Figure 18 shows the potential plague buildup that can occur on a nonocclusal surface of a restoration.

Artificial Solutions in Corrosion and Tarnish Testing. As already indicated, the interior surfaces of restorations are exposed to the interstitial fluids and the exterior surfaces to the salivary fluids. A physiological saline solution, such as Ringer's which contains a Cl^- concentration of about seven times larger than artificial saliva, is therefore more appropriate for simulating *in vivo* interior surfaces in laboratory testing methodologies. The O_2 content should be reduced to simulate *in vivo* levels in dentin. The use of Ringer's and even higher Cl^- concentrations is appropriate for the testing of corrosion that may occur within marginal crevices of restorations, because crevices can become chloride-rich and acidified. However, applying these results to the corrosion occurring on exterior surfaces of restorations may not be appropriate, even when considering that the increased Cl^- corrosion with Ringer's solution would be an even more stringent test and that the results would correspond to maximum corrosion conditions.

An artificial saliva is more appropriate for testing the corrosion of the exterior surfaces of restorations. The artificial saliva should take into account most of the species contained in saliva and not just a selected few that have been known to affect alloy corrosion. The artificial saliva should include the capabilities for generating organic films on the surfaces, even though their effects in isolated tests may prove unimportant. In order to simulate oral environment conditions the tarnishing of the exterior surfaces of restorations, an artificial saliva incorporating sulfide is appropriate. Even though the normal sulfide concentrations contained in saliva are within low ranges, accumulations of sulfide can occur along and within crevices to justify the use of higher than normal concentrations. However, the sulfur peak intensities detected with secondary ion mass spectroscopy (SIMS) on alloy surfaces exposed to low levels of sulfide solutions were similar to those from solutions containing higher sulfide concentrations. However, the alloy surface color changes responded more to higher sulfide concentrations.

Classification and Characterization of Dental Alloys

As indicated in the introduction to this article, a wide range of dental alloys exist. This selection will review the following types of alloys available for dental applications:

- Direct filling alloys
- Crown and bridge alloys
- Partial denture alloys
- Porcelain fused to metal alloys
- Wrought wire alloys
- Soldering alloys
- Implant alloys

The effects of composition and microstructure on the corrosion of each alloy group will be discussed. Additional information on tarnishing and corrosion behavior of these alloy is discussed in the section "Tarnish and Corrosion Under Simulated or Accelerated Conditions" in this article.

Direct Filling Alloys

Amalgams. Two types of amalgams are used: low copper (referred to as conventional) and high copper. The alloy particles of the low-copper type are all of the single-particle variety, whereas the high copper type can also be of the dispersed particle variety.

Amalgams are produced by combining mercury with alloy particles by process referred to as trituration. About 42 to 50% Hg is initially triturated with the high-copper types, while increased quantities of mercury are used with the low-copper types. High-speed mechanical amalgamators achieve mixing in a matter of seconds. The plastic amalgam mass after trituration is inserted into the cavity by a process of condensation. This is accomplished by pressing small amalgams increments together until the entire filling is formed. For amalgams using excess mercury during trituration, the excess mercury is condensed to the top of the setting amalgams mass and scrapped away. Dental amalgam alloys can become certified by complying with the requirements of American National Standards Institute (ANSI)/American Dental Association (ADA) Specification No. 1, which covers alloys for dental amalgams (Ref 106, 107). Table 5 presents compositions for a number of different amalgam alloys.

Table 5 Compositions of some dental amalgam alloys

Alloy	Composition, wt%			
	Ag	**Sn**	**Cu**	**Zn**
Low-copper				
Cresilver	75.0	24.6	0.1	0.3
Pure Lab	72.0	26.0	1.0	1.0
New True Dentalloy	72.8	26.2	2.4	1.0
Microalloy	69.0	26.6	3.5	0.9
Lustralloy	68.0	26.0	5.1	0.9
High-copper-dispersed				
Optalloy II	69.8	20.0	9.7	0.5
Dispersalloy	69.3	18.1	11.6	1.0
Cluster	69.8	16.2	13.5	0.5
Phasealloy	62.0	18.5	18.5	1.0
Cupralloy	63.5	16.9	19.5	0.2
High-copper-single				
Tytin	59.5	27.6	12.2	0
Indiloy	60.0	22.0	13.0	(5.0 In)
Valiant	49.5	30.0	20.0	(0.5 Pd)
Cupralloy ESP	41.0	32.5	26.5	0
Sybralloy	40.0	31.2	28.8	0

Low-Copper Conventional Amalgams. The alloy particles with the low-copper type are basically Ag_3Sn, the γ phase of the Ag-Sn system, even though smaller amount of the β phase, a phase richer in silver, may also be present. Copper can be added in amounts up to about 5 wt% and zinc up to 1 to 2%. About 2 to 4% Cu is soluble in Ag_3Sn, while the additional copper usually precipitates as Cu_3Sn, the ϵ phase of the Cu-Sn system, although amounts of Cu_6Sn_5, the η' phase, may also occur. The low-copper particles are mostly lathe cut irregular, although spherical atomized particles are also used. The amalgamation reaction for a low-copper amalgam is:

$$Ag_3Sn\text{-}Cu_3Sn\text{-}Zn + Hg \rightarrow Ag_{22}SnHg_{27} + Sn_8Hg + Ag_3Sn\text{-}Cu_3Sn\text{-}Zn \text{ (unreacted)} \quad \textbf{(Eq 6)}$$

In Eq 6, Ag_3Sn with Cu_3Sn and zinc react with mercury to form two major reaction products of $Ag_{22}SnHg_{27}$ (the γ phase of the Ag-Hg system with dissolved tin and referred to as the γ_1 amalgam phase) and Sn_8Hg (the γ phase of the Sn-Hg system and referred to as the γ_2 amalgam phase) (Ref 108). Unreacted Ag_3Sn with Cu_3Sn and zinc particles are held together in a γ_1 matrix with γ_2 interspersed within the matrix. Typical distributions of the phases range up to about 30 wt% for γ, 60 to 80% for γ_1, 5 to 30% for γ_2, and up to about 3% for ϵ (Ref 109). Very minimal η' may also form. Zinc is generally distributed uniformly throughout material. Porosities are in all amalgam structures. As high as 6 to 7 vol% occur with some systems (Ref 110). Interconnection of the γ_2 phase throughout the bulk may also occur (Ref 111). Transformation of the γ Ag-Hg (γ_1 amalgam phase) to the β Ag-Hg phase (β_1 amalgam phase) can also occur with aging (Ref 112). However, because of the dissolved tin in the γ_1 structure, stability is increased. Figure 20 presents the microstructure of a polished low-copper amalgam.

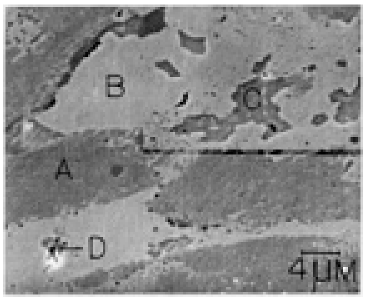

Fig. 20 SEM micrograph of polished, etched, and partially repolished low copper amalgam (Minimax). A, γ; B, γ_1; C, γ_2; D, porosity

High-Copper Amalgams. The alloy particles with the high-copper dispersed-phase type are blends of conventional particles with basically spherical silver-copper eutectic particles in the proportion of about 3 to 1, respectively. The dispersed particles can be composed of a variety of silver-copper compositions, with other alloying elements, and combined in varying proportions with the conventional particles.

The alloy particles with the single-particle high copper are compositions that can contain up to 30% Cu and more. The particles are mostly atomized into spherical shape.

The setting reaction for high-copper dispersed phase amalgam is:

$$Ag_3Sn\text{-}Cu_3Sn\text{-}Zn + Ag\text{-}Sn + Hg \rightarrow Ag_{22}SnHg_{27} + CU_6Sn_5 + Ag_3Sn\text{-}Cu_3Sn\text{-}Zn \text{ (unreacted)} + Ag\text{-}Cu \text{ (unreacted)} \qquad \textbf{(Eq 7)}$$

and for high-copper single-particle amalgam is:

$$Ag_3Sn\text{-}Cu_3Sn\text{-}Zn \rightarrow Ag_{22}SnHg_{27} + Cu_6Sn_5 + Ag_3Sn\text{-}Cu_3Sn\text{-}Zn \text{ (unreacted)} \qquad \textbf{(Eq 8)}$$

For dispersed-phase amalgam, γ initially reacts with mercury to form γ_1 and γ_2 phases, as with the low-copper amalgam. However, an additional reaction occurs between γ_2 and the silver-copper particles to form η' and additional γ_1. The η' phase forms reaction rings around the dispersed particles as well as islands of reaction phase within γ_1 matrix. Figures 21 and 22 present the microstructure of a dispersed-phase amalgam and EDS x-ray mapping for silver, mercury, tin, and copper, respectively.

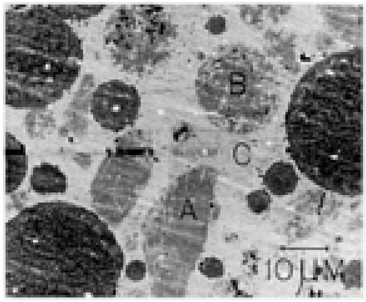

Fig. 21 SEM micrograph of polished, etched, and partially repolished high-copper dispersed-phase amalgam (Cupralloy). A, γ; B, Ag-Cu; C, γ_1. See also Fig. 22.

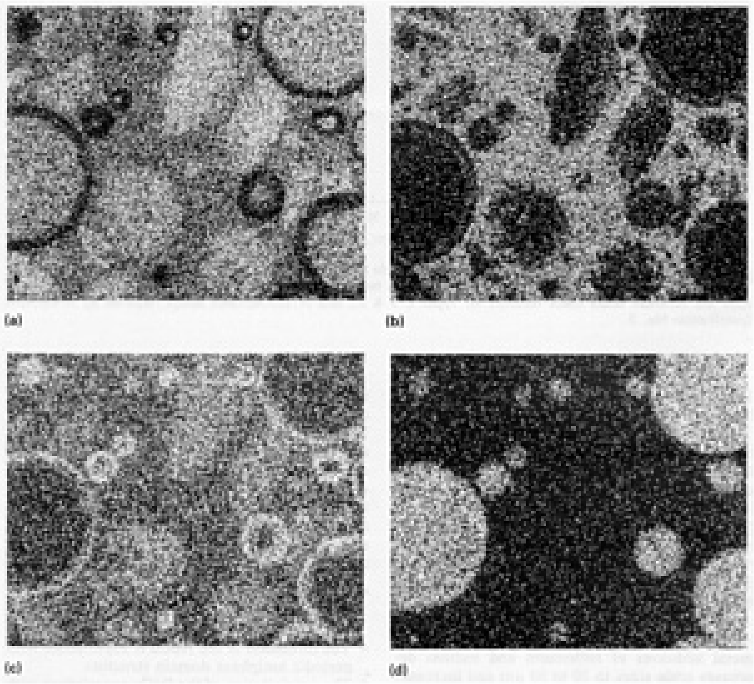

Fig. 22 Elemental maps obtained by energy-dispersive spectroscopy of the high-copper amalgam shown in Fig. 21. (a) EDS mapping for silver. (b) EDS mapping for mercury. (c) EDS mapping for tin. (d) EDS mapping for copper

For single-particle high-copper amalgam, reaction of the initially formed γ_2 phase occurs with the ϵphase of the original alloy particles instead of with a dispersed particle to form the η' phase again. The γ_1 phase is likely to become tin enriched. Reaction zones around the original alloy particles, as well as products within the matrix, occur.

Figure 23 shows the microstructure of a polished, etched, and slightly repolished high-copper single-particle amalgam that shows primarily the distribution of the η' phase. The elimination of γ_2 phase and the subsequent formation of η phase are time dependent and are dependent on the amalgam system (Ref 113). For fast reacting amalgams, formation of η' may be complete within hours, while for slower reacting systems, η' may continue to form for months. The single-particle high-copper amalgams contain higher percentages of the η' phase and lower percentages of the γ_2 phase, although all high-copper amalgams contain minimal γ_2 relative to conventional amalgams. Porosities with the high-copper amalgams can be up to approximately 5 vol % and with a smaller size distribution than with the conventional type (Ref 110). The γ_1 to β_1 transformation can also occur to a limited extent. With the high-copper amalgams, both indium (5%) and palladium (0.5%) containing amalgams add specific characteristics to the amalgams and have gained limited use.

Crown and Bridge and Partial Denture Alloys

High Nobility Alloys. Gold-base alloys for cast appliances have traditionally been based on the chemical compositional requirements of ANSI/ADA Specification No. 5, which covers gold dental casting alloys (Ref 114). This specification requires a minimum of 75 wt% Au plus platinum group metals. Alloys meeting the requirements of the specification became known as the conventional alloys, of which there were Types I to IV (Table 6). This requirement has served to reject alloys that would have tarnished in the mouth. Some alloys that have complied with the compositional requirement were, however, found to tarnish in the mouth, while others with lower nobility were developed with very good tarnish resistance. As a result, Specification No. 5 may be subject to revisions.

Composition of High Nobility Alloys. The primary alloys elements of high nobility alloys are gold, silver, and copper, along with additions of palladium, platinum, and zinc, as well as grain-refining elements, such as rubidium and iridium. Figure 24 shows the compositions for about 75 currently available dental casting alloys projected onto a pseudo (Au, Pd, Pt)-Ag-Cu ternary diagram. Actually, all of the compositions shown are referred to as low gold content alloys, which are covered in the following section. Also shown in Fig. 24, near the gold + platinum group metal apex, are dashed

lines referring to the minimum nobility content of the four types (I to IV) of conventional alloys from the existing ANSI/ADA Specification No. 5. High, medium, and low nobility alloys are currently used. High and medium nobility alloys refer to compositions with gold plus platinum group metal contents greater than 75 wt%, while the low nobility alloys refer to compositions with less than 75 wt% Au plus platinum-group metals. Table 6 includes composition for number of high and low gold content alloys.

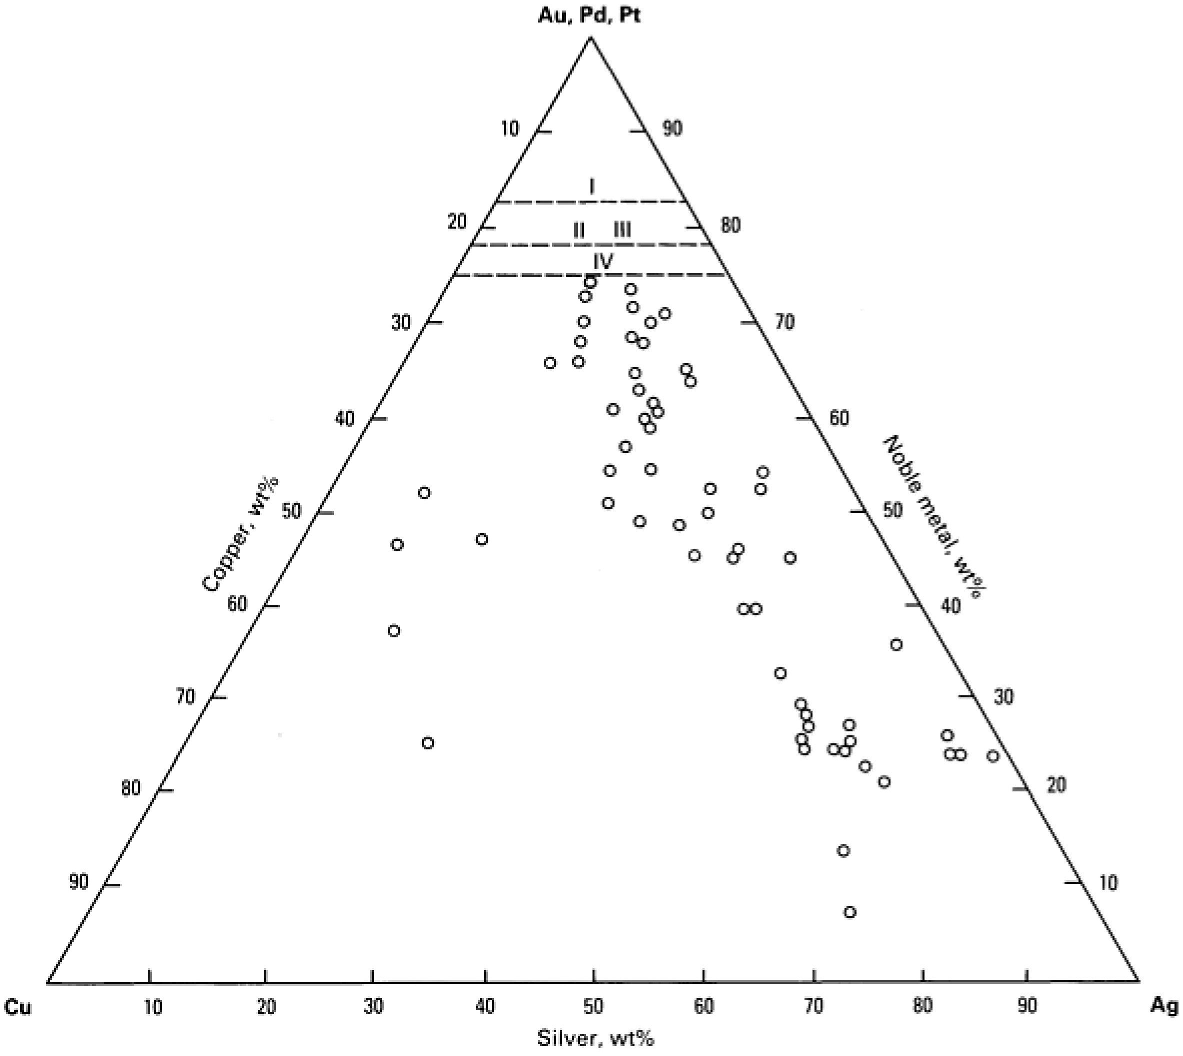

Fig. 24 Compositions of some commercially available low gold content crown and bridge alloys projected onto a pseudo noble metal (Au, Pt, Pd)-Ag-Cu ternary phase diagram. Also shown near the noble metal apex are minimum noble metal contents for Types I, II & III, and IV conventional alloys required by ANSI/ADA Specification No. 5.

For the most part, properties of the high nobility cast dental alloys follow similar patterns as those shown by the gold-silver-copper ternary alloys, although the additional alloying elements in the dental alloys have significant effects on properties. Because the high nobility alloys have relatively small liquidus-solidus gaps, casting segregations, inhomogeneties, and coring effects are not major problems. Microstructurally, single-phase structures predominate because compositions fall within the single-phase region of the Au-Ag-Cu system. Grain refinement by the noble metal additions of ruthenium and iridium decreases grain sizes 20 to 50 μm and increases strengths and elongations by about 30 and 15%, respectively (Ref 116).

Hardening Mechanisms of High Nobility Alloys. Type III and IV cast alloys, which are used for restorations subjected to high biting stresses, can be hardened by heat treatment. The primary hardening mechanism in gold dental alloys is by disorder-order superlattice transformations of the Au-Cu system. The ordered domains of the Au-Cu system also extend into the ternary phase Au-Ag-Cu regions. Typically heat treatment times and temperatures are 15 to 30 min at

350 to 375 °C (660 to 705 °F). Often, it is adequate to bench cool the casting in the investment after casting to gain hardness. Because of the complexity of the dental gold alloy compositions, the exact hardening mechanisms depend on the particular composition of the alloys. Table 7 presents a schematic representation of the age-hardening mechanisms and related microstructures occurring in gold dental alloys. Included are representations for high-gold alloys (HG), low-gold alloys (LG), gold-silver-palladium base alloys (GSP), and 18 karat and 14 karat gold alloys. Five types of phase transformations are found (Ref 117):

- The formation of the AuCu I ordered platelets and twinning characterized by a stair-step fashion
- The formation of the AuCu II superlattice with periodic antiphase domain structure
- The precipitation of the PdCu superlattice with face-centered tetragonal (fct) structure analogous to the AuCu I
- Spinodal decomposition giving rise to a modulated structure
- The formation of the lamellae structure developed from grain boundaries by discontinuous precipitation

Table 7 Hardening mechanisms for some dental alloys

The hatched areas represent the hardness peaks on aging. (9/5) °C + 32 °F.

Low Nobility Alloys. Ever since the increases in the gold prices have taken place, new economy golds with lower gold contents have been introduced and have become popular. Figure 25 shows the trends in sales of dental casting alloys in the United States from 1976 to 1981. In a more recent survey of 488 dental laboratories, 46.5% of the responses indicated that only 0 to 25% of the crown and bridge alloys that they processed contained gold. Only 27.9% responded that 51% or more of their alloys contained gold (Ref 119).

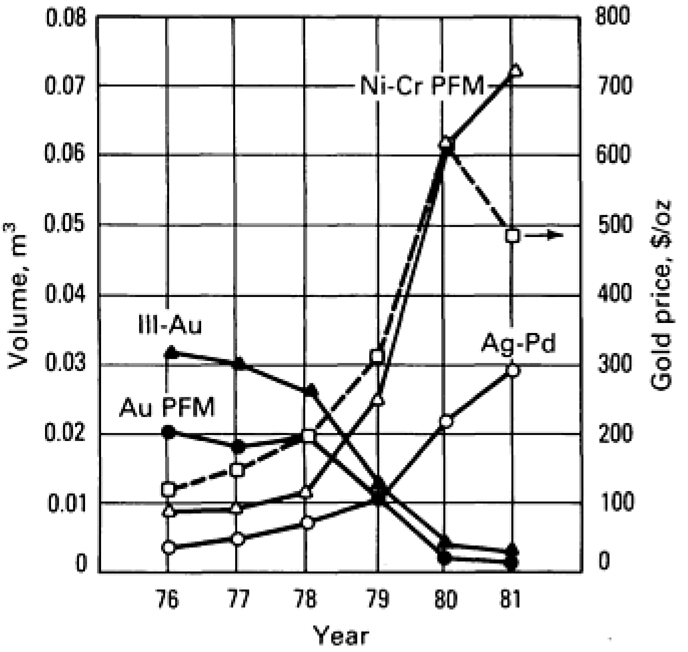

Fig. 25 Trends in alloy use along with the market price of gold for the years 1976 to 1981. Source: Ref 118

Compositions of Low Nobility Alloys. Low noble metal alloys comprise a wide variety of compositions (Table 6). Gold-, palladium-, silver-, and copper-base alloys are used. Platinum and zinc contents are usually held to several weight percent maximum, if present. Microstructurally, the low gold content casting alloys are complex, and examination of phase diagrams of either the Au-Ag-Cu or Ag-Pd-Cu ternary systems indicates that the liquidus-solidus gaps between the various phases can be large (Ref 116). Therefore, coring and casting segregations occur upon solidification during casting. The alloys are characterized by dendritic structures combined with additional phases located within interdendritic positions. Both silver- and copper-rich segregations occur. The presence of gold, platinum, zinc, and other alloying elements further complicates the structures.

The addition of palladium and zinc to the Au-Ag-Cu alloy systems makes heat treatments to single-phase structures difficult. In silver-rich phases, the solubility limit for palladium and zinc is only about 1 to 2% at 500 °C (930 °F), while for copper-rich phases, solubilities are much higher--of the order of 10%. Therefore, precipitation of palladium- and zinc-rich phases occurs. Differences also occur in the gold contents between the phases with the copper-rich phases having the higher contents (Ref 120).

Silver palladium base alloys with additions of copper, gold, and zinc are also complex and contain multiple phases. Microstructurally these alloys are characterized by silver-rich matrices interspersed with Pd-Cu-Zn enriched compounds. As many as three different Pd-Cu-Zn compounds have been detected in one alloy system. The Pd-Cu-Zn compounds are actually composed of two face-centered cubic (fcc) phases in addition to a body-centered cubic (bcc) $PdCu_xZn_{x-1}$phase. In addition, the silver-rich matrixes are normally cored with silver-enriched dendritic arms and copper segregations in the interdendritic areas (Ref 121).

The hardening mechanisms associated with the low nobility alloys are shown in Table 7. In addition to the gold-copper disorder-order transformations, ordering due to the palladium-copper superlattices is also usually involved because of replacement of some of the gold by palladium.

Silver-indium alloys with small additions of palladium or gold have also been used for crown and bridge applications. Figure 26 presents microstructures for a number of low-gold alloys.

Base Metal Alloys. Most of the base metal alloys for all metal cast crowns and bridges are composed of nickel-chromium alloys, although stainless steels are also used, particularly outside of the United States. Nickel-chromium alloys are also used for the construction of partial dentures. However, cobalt-chromium alloys far exceed any other alloy for use in this application. Titanium alloys are also being developed for dental applications. Table 8 presents the compositions for a number of base metal alloys intended for crown and bridge, partial denture, porcelain fused to metal, and implant applications.

Nickel-Chromium Alloys. The primary alloying element with the nickel-base alloys is chromium between about 10 and 20 wt%. Molybdenum up to about 10%; manganese and aluminum up to about 4% each; and silicon, beryllium, copper, and iron up to several percent each can also be added. The carbon contents range between about 0.05 and 0.4%. Elements such as gallium, titanium, niobium, tin, and cobalt can also be added. Because of differences in properties required for crown and bridge applications versus partial denture applications, minor modifications in compositions occur between nickel-chromium alloys intended for the two applications. This is reflected by the fact that crown and bridge nickel-chromium alloys contain higher percentages of iron, very minimal or no aluminum and carbon, and copper additions (Ref 131).

Chromium and molybdenum are added for corrosion resistance. In order to be effective, these elements must not be concentrated along grain boundaries. Chromium contents below about 10% deplete the interior of the grains leading to corrosion. Molybdenum protects against concentration cell corrosion, such as pitting and crevice corrosion, and is also a solid-solution hardener. Manganese and silicon are reducing agents, while aluminum also improves corrosion resistance and improves strength through its formation of intermetallic compounds with nickel. Silicon, like beryllium and gallium, lowers the melting temperature. Beryllium is also a solid-solution hardener and improves castability. Niobium, like molybdenum and iron, affects the coefficient of thermal expansion. Gallium is a stabilizer and improves corrosion resistance. The oxide-forming elements and the elements promoting good bond strength to porcelain will be discussed in the section "Porcelain Fused To Metal Alloys" in this article.

Although the compositions for many of these alloys are similar, differences occur with regard to microstructure and properties. In comparing the microstructures of four different commercial nickel-chromium alloys, it was noted that one of the alloys had thin, elongated carbides and intragranular precipitates adjacent to grain boundaries. A second alloy showed discontinuous spherical carbides, the third showed a continuous grain-boundary phase and cored dendrites, and the fourth showed a dendritic precipitate (Ref 132). In another alloy, the dark interdendritic carbides changed to a lamellar pattern at certain sites and were surrounded by dispersed carbide particles and the δ' phase of Ni_3Al (Ref 133). Heat treatments were shown to have drastic effects on the microstructures of several as-cast nickel-chromium alloys (Ref 134).

Cobalt-Chromium Alloys. The primary alloying element with the cobalt-base alloys is chromium between about 20 to 30%. Molybdenum is also present in amounts up to about 10%; small additions of elements such as silicon, manganese, iron, and nickel are sometimes also present. The carbon contents usually range between about 0.05 and 0.4% (Ref 131).

This composition forms the basis for two additional generalized compositions. The first includes a group of alloys that has been developed from the above basic composition, but with each modified by the addition of one or more elements in order to obtain a particular range of properties (Ref 135). Some of these modifying elements include gallium, zirconium, boron, tungsten, niobium, tantalum, and titanium.

The second generalized composition includes replacement-type alloys, with a major portion of the cobalt replaced by nickel and/or iron. The resulting composition is a cross between cobalt-base alloys and stainless steels. The effects of the individual elements on the properties of the alloys are similar to those already discussed for the nickel-chromium alloys. The alloys are hardened primarily by carbide formation. Therefore, the carbon content is of primary importance.

A number of carbides, including MC, M_6C, M_7C_3, and $M_{23}C_6$, have been detected in dental cobalt-chromium alloys (Ref 136). Solid-solution strengthening also occurs, as well as intermetallic compound formation strengthening, with a number of the modified alloy types. Certified alloys for partial dentures must contain a minimum cobalt-chromium-nickel content of 85% with a minimum of 20% Cr as required by ANSI/ADA Specification No. 14 for dental base metal casting alloys (Ref 137).

Microstructurally, the cobalt-chromium alloys are typified by a cored austenitic solid-solution matrix interspersed with isolated carbides, such shown in Fig. 27. However, depending on compositions, the microstructures can vary considerably. In comparing the microstructures of a number of different cobalt-chromium alloys, the unmodified alloys with the basic composition given above exhibited large grains, with both large and small carbides being, respectively, either randomly dispersed or precipitated along grain boundaries (Ref 135). For the modified alloys containing additional alloying elements, the grain sizes were smaller than for the unmodified materials, with the carbides dispersed within the grains rather than being precipitated along grain boundaries.

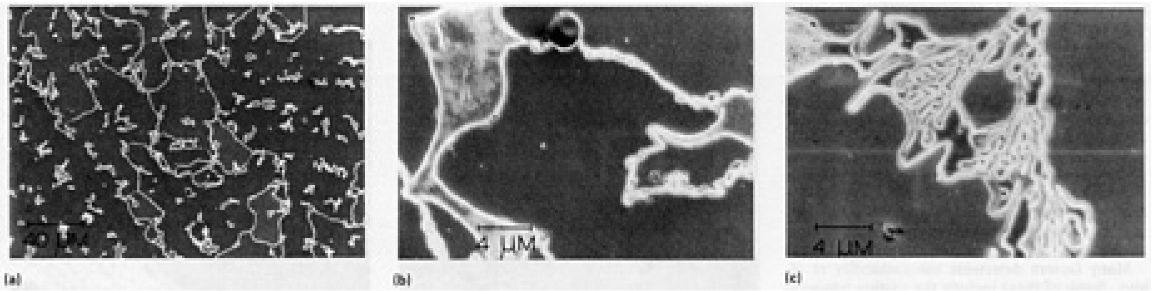

Fig. 27 SEM micrographs of etched cobalt-chromium partial denture alloys. (a) and (b) Neoloy. (c) Nobillium.

The microstructures for modified cobalt-chromium alloys were analyzed in greater detail (Ref 138). For one typical alloy, the underlying matrix had the highest cobalt concentration with lowest chromium and molybdenum concentrations. The numerous continuous precipitates located along grain boundaries were moderately high in cobalt and low in chromium and molybdenum. The dark areas within the grain interiors contained high carbon, moderately high chromium and molybdenum, and low cobalt. Dispersed precipitates located within the matrix had high chromium and molybdenum contents and low cobalt.

An extensive project was undertaken regarding the development of a new dental superalloy system (Ref 139). The outcome of the project indicated that a cobalt-base alloy with desirable properties for dental applications could be made from a 40Co-30Ni-30-Cr matrix. The alloy is strengthened by the precipitation of coherent intermetallic compounds of tantalum. Alloys that are stronger and more ductile than conventional dental alloys were obtainable. The results were reinvestigated, and it was again concluded that tantalum does improve the properties somewhat (Ref 140).

Stainless Steel Alloys. At least one alloy (Dentillium) is commercially available for crown and bridge applications (Table 8). This alloy, as well as its modified version for partial denture applications, is an iron-base composition with 24 to 28% Cr, 6 to 8% Co, 4 to 6% Ni, and 2.5% Mo. Microstructurally, two phases exist (Ref 138). The matrix is high in chromium, molybdenum, iron, and cobalt and is low in nickel, but the precipitates are high in nickel and reduced in chromium, molybdenum, iron, and cobalt. Stainless steel preformed crowns are also occasionally used for temporary restorations.

Titanium-Base Alloys. Cast titanium alloys have only within about the past decade been shown to possess potential for crown and bridge and partial denture applications, as well as for porcelain bonding. Because titanium alloys have high melting temperatures, casting of these alloys has not been possible until recently in the dental laboratory. The introduction of a lower-melting titanium alloy has made this requirement achievable (Ref 141). The first alloy to be successfully cast had a composition of 82Ti-13Cu-4.5Ni with a melting temperature of 1330 °C (2426 °F). The introduction of an argon/electric arc vertical centrifugal casting machine and a vacuum-argon electric arc pressure casting machine made the casting of the higher melting point titanium alloys also achievable. Pure titanium and Ti-6Al-4V have been successfully cast by these latter methods (Ref 142). Better investment materials are currently being developed.

Copper-Aluminum Alloys. The copper-aluminum restorative alloys have elicited renewed interest because of their similarity in appearance to the yellow gold alloys and because of the volatility of gold prices. The compositions include copper base, with about 10 to 20% Al, and up to approximately 10% iron-manganese nickel (Table 8). The as-cast etched structures are dendritic.

Alloy Color. Color is a surface characteristic that is related to alloy composition. Although color by itself has no affect on biocompatibility and the properties of the alloy, it has become equated with quality for many people, including some professionals. Alloy color remains an important issue. The white golds are held by many to be inferior to the yellow golds. The significance of yellow color as an indicator of alloy quality is so strong that a number of nonnoble yellow alloys, such as copper-aluminum, that resemble gold alloys in appearance and lack tarnish resistance have become available.

Yellowness in dental gold alloys is imparted by the gold and copper. Absence of yellowness is no assurance that the alloy is lacking gold or copper content. Color can be a misleading indicator of composition. For example, some dental gold alloys for porcelain fused to metal restorations contain more than 80% Au, yet yellowness is absent because of the strong whitening effect of palladium and platinum. Detailed information on alloy color and the characterization of dental alloys by colorimetry can be found in Ref 105, 143, and 144, 145, 146, 147, 148, 149.

Factors Related to Casting. Dental alloys must be cast into thin sections and intricate shapes in order to produce the margins and curvatures on restorations and to provide an accurately fitting casting. The castability of dental alloys is evaluated by the ability to be cast into shapes, such as wedges, spirals, rods of various shapes, and mesh grids of various sizes. The casting accuracy is usually evaluated by the degree of fit a finished casting possesses with a master die.

Many factors determine the castability of alloys. Some of these include the casting temperature and surface tension of the molten alloy as well as many variables associated with the casting technique, some of which include wax pattern preparation, position of the pattern in the casting ring, techniques used in alloy heating, and centrifugal casting force. Some factors affecting casting accuracy include the thermal contraction of the alloy as a result of going from liquid to room temperature, the effectiveness of investment material to compensate for the thermal contraction of the alloy, anisotropic contractions, and the roughness of the casting.

There are indications that the base metal castings produce inferior fits for crown and bridge uses as compared to castings made from conventional gold alloys (Ref 150). Low-gold alloys with about 50% Au generated fits that were satisfactory. Part of the problem with the base metal alloys may be the use of casting techniques that were developed for the gold alloys.

Casting porosity is another important factor in the casting process. Although casting technique variables affect porosity contents, alloy composition can also affect porosity. One way in which composition affects porosity is the generation of internal shrinkage pores between microstructural phases in complex multiphase alloys. This microporosity weakens alloys, makes finishing and polishing more difficult, and is a prime factor in tarnishing. Palladium in alloys is susceptible to occluding gases from the melt. Therefore, palladium-containing alloys have the potential for becoming affected mechanically through embrittlement.

Porcelain Fused to Metal Alloys

Stringent demands are placed on the alloy system meant to be used as a substrate for the baking on or firing of a porcelain veneer. The thermal expansion coefficients of alloy and porcelain must be matched so that the porcelain will not crack and break away from the alloy as the temperature is cooled from firing temperature to room temperature. Thermal expansion coefficients of porcelains are in the range of 14×10^{-6} to 15×10^{-6}in./in. °C. Selection of an alloy with a slightly larger coefficient by about 0.05% is recommended so that the alloy will be under slight compression.

The alloy must be high melting so that it can withstand the firing temperatures involved with the porcelain. However, the temperature must not be excessively high so that conventional dental equipment can still be used. A temperature of 1300 to 1350 °C (2370 to 2460 °F) is about maximum. The porcelain firing procedures require an alloy with high hardness, strength, and modulus so that thin sections of the alloy substrate can support the porcelain, especially at the firing temperatures.

High mechanical properties are also required for resisting sag of long span bridge unit assemblies during firing. The alloy should also have the ability to absorb the thermal contraction stresses due to any mismatch in expansion coefficients as well as occlusal stresses without plastic deformation. Therefore, too high of a modulus for a material with an insufficient yield strength is contraindicated, although too high of an elastic deformation is also contraindicated. High bond strengths are required so that the porcelain veneers remain attached to the alloy. The alloy system must also be chemically compatible with the porcelain. Alloying elements must not discolor porcelain, yet must have tarnish and corrosion resistance to the fluids in the oral environmental. The compositions for a number of porcelain fused to metal (PFM) alloys are presented in Table 9.

Table 9 Compositions of noble metal porcelain fused to metal alloys

In order to promote and form high bond strengths between porcelain and alloys, the alloy must have the ability to form soluble oxides that are compatible with the porcelain. At the firing temperature, the porcelain should spread or wet the surface of the alloy. Therefore, both mechanical and chemical interactions are involved in this process. In order to promote chemical interactions, specific oxide-forming elements, such as tin, indium, or gallium, are added to the alloy in low concentrations. The addition of iron, nickel, cobalt, copper, and zinc provide the means for hardening.

Alloy color with the PFM alloys is not as demanding as with the crown and bridge alloys because the alloy is masked by the porcelain veneer. However, the margins between metal and porcelain can still be seen. This consideration still makes the yellow alloys more aesthetically pleasing, especially for anterior restorations. White alloys have the effect of producing a grayish color.

The fabrication of the PFM restoration consists of a complex set of processes. After casting, the alloy substrate is subjected to a preoxidation heat treatment to achieve the optimum surface oxides that are important for porcelain bonding. As many as three or more different porcelain firings follow. These include a thin opaque layer adjacent to the alloy, followed by body porcelain layers, including both dentin and enamel porcelain buildups. The opaque layer should mask the color of the alloy from interfering with the appearance of the porcelain. The body porcelain layers build up the restoration to the desired occlusion. The alloy-porcelain systems are slowly cooled from firing temperatures to accommodate dimensional changes occurring in both alloy and porcelain. Therefore, the alloy substrates are subjected to a number of temperature cycles during processing that affect their microstructure and properties. The slow cooling cycles also permit the formation of the compounds important for hardening of alloys.

Noble Metal PFM Alloys. The evolution of alloys for the PFM restoration has generated at least four different noble alloy systems. These are classified as gold-platinum-palladium, gold-palladium with and without silver, silver-palladium, and high-palladium content alloys(Ref 116, 140, 157, 158).

Gold-Platinum-Palladium PFM alloys. The compositions of alloys included within this group are in the range of 80 to 90% Au, 5 to 15% Pt, 0 to 10% Pd, and 0 to 5% Ag, along with about 1% each of tin and indium. Other additions may include up to about 1% each of iron, cobalt, zinc, and copper. Platinum and palladium additions increase melting temperature and decrease thermal expansion coefficients, with platinum having the added effect of hardening the alloy.

Iron is the principal hardening agent. Iron promotes the formation of an ordered iron-platinum type intermetallic phase that forms between 850 and 1050 °C (1560 and 1920 °F) upon cooling from the firing temperature (Ref 116). The ordered phase is finely dispersed throughout matrix. Iron, along with tin and indium, promotes bonding to porcelain by diffusing into the porcelain up to about 60 μm at the firing temperature. Tin and indium also promote solid-solution strengthening. Alloys within this group range in color from light yelllow to yellow.

Even though these alloys have many advantages, their high cost and low sag resistances have necessitated the development of additional alloy systems. Unless they are used in thick sections, for example, 3 × 3 mm (0.12 × 0.12 in.), plastic deformation of long spans will occur during firing.

Gold-Palladium and Gold-Palladium-Silver PFM Alloys. Gold-palladium with and without silver alloys were developed as alternatives to the costly gold-platinum-palladium alloys. The Au-Pd-Ag system was one of the first alternative systems. Up to 15% Ag and 30% Pd replaced all of the platinum and a large fraction of the gold from the Au-Pt-Pd system, which resulted in substantial cost savings. The gold-palladium-silver alloys possessed better mechanical properties for the PFM restoration. Because gold-palladium, gold-silver, and palladium-silver are all solid-solution alloys, the ternary Au-Pd-Ag system also forms a series of solid-solution alloys over the entire compositional ranges. Therefore, the matrices of the gold-palladium-silver dental alloys are single phase. Up to 5% Sn is added, which hardens the alloy by forming compounds with palladium that are dispersed throughout matrix. Tin is also and oxide former and bonding agent with porcelain. Because platinum was avoided, there was no need to incorporate iron for hardening. Their shortcoming was the ability of silver from the alloy to vaporize, diffuse, and combine with the porcelain at the firing temperature, thus including color changes, mostly greenish, along the alloy-porcelain margin. Sodium-containing porcelains were more susceptible to this color change.

The development of the silver-free gold-palladium alloys eliminated the discoloration of the porcelain. Their compositions cover a wide range: 50 to 85% Au, 10 to 40%Pd, 0 to 5% Sn, and 0 to 5% In, along with possible additions from zinc, gallium, and other elements. The alloy matrix is based on the Au-Pd binary system, which is of the solid-solution type. Hardening is due to Pd-(In, Sn, Ga, Zn) complexes that the disperse throughout the matrix. Microstructurally, a fire network of gold-rich regions are entwined by second-phase particles of Pd-(Sn, In, Ga, Zn). Their color is only a pale yellow, unlike some of the deeper yellow gold-platinum-palladium alloys. However, about a 30 to 40% cost savings is obtained. Their mechanical properties are superior, which means good sag resistance at the firing temperatures. The only disadvantage with these alloys is their lower thermal expansion coefficients when used with some of the higher-expanding porcelains.

Some newer gold-palladium alloys have up to 5% Ag, which is much lower than the 15% contents used with the original gold-palladium-silver alloys. This results in better thermal expansion matches with porcelain and avoids the discoloration problem with porcelain because of the lower silver concentrations. The gold-palladium alloys have gained a large percentage of the PFM alloy market.

Palladium-Silver PFM Alloys. These alloys were developed out of the need to reduce the cost of the PFM restoration even more than from those fabricated from gold-palladium alloys. Compositions range from 50 to 60% Pd, 25 to 35% Ag, 5 to 10% Sn, 0 to 5% In, and up to 2% Zn. The silver and palladium contents are just about reversed in magnitude as compared to those compositions used with the silver-palladium crown and bridge alloys discussed earlier in this article.

The microstrutures of the alloys are based on the Pd-Ag solid-solution system. Instead of using copper to harden the alloys, hardening occurs through compounds formed between palladium and tin, indium, zinc, and others. Hardening rates are high, which indicates nondiffusional reactions. It is likely that hardening occurs by ordering processes that form by spinodal decomposition (Ref 116). Oxides are imparted to the alloy surface because of the oxide-forming ability of indium, tin, and zinc alloying additions. This promotes high bond strengths. The mechanical properties of the palladium-silver alloys, along with the high-palladium alloys discussed below, are superior to those of any other system, excluding the nickel-chromium alloys. As with the gold-palladium-silver alloys, the chief disadvantage is the ability of silver to discolor porcelains during firing. In order to overcome this problem, various methods have been used, including, coupling agents composed of porcelains or colloidal gold.

High-palladium PFM. These alloys represent the most recent developments in alloys for PFM restorations (Ref 159, 160, 161, 162, 163, 164). Their compositions are 75 to 85% Pd with 0 to 15% Cu, 0 to 10% Ga, 0 to 8% In, 0 to 5% Co, 0 to 5% Sn, and 0 to 2% Au. The alloys are based on either the Pd-Cu-Ga or the Pd-Co-Ga ternary systems. Regardless of the high copper contents, these alloys do not induce porcelain discoloration and bonding problems. Many of these alloys have better workability than other types of PFM alloys, while retaining high hardnesses. The hardness is dependent on the formation of intermetallic compounds with palladium upon cooling from the firing temperature. The alloy forms strong

bonds with porcelain because of the alloy oxidizer content. Oxides form with palladium and the alloying additives. However, palladium oxide (PdO) forms only during heating and cooling because of the relatively low decomposition temperature for the oxide. The oxide-forming ability of the added oxidizers is dependent on alloy composition, temperature, and time, Indium, gallium, and cobalt oxidize preferentially, while copper and tin show non-preferential oxidation. Cobalt suppressed the oxidation for copper and tin in one alloy system (Ref 160).

The palladium-gallium eutectic dominates the alloy systems. Additions of both indium and copper reduce the solid solubility of gallium so that the eutectic forms at lower gallium contents (Ref 154). Microstructurally, as-cast structures are dendritic, with moderate compositional variations occurring due to coring. The interdendritic regions contain higher amounts of alloying elements. For a palladium-copper-gallium alloy, the interdendritic precipitates are fcc with the composition of $Pd_3Ga_xCu_{1-x}$ (Ref 164). Upon cooling below 500 °C (930 °F), an ordered fct structure forms rapidly. This lattice straining produces the high hardnesses and yield strengths characteristic of these materials.

Base metal PFM alloys are primarily composed of the nickel-chromium alloys. Cobalt-chromium alloys are also used, but they constitute only a very small percentage of base metal use for PFM. Titanium-base alloys are currently being developed for PFM usage.

The nickel-chromium PFM alloys are very similar, if not the same, as the compositions of the nickel-chromium alloys used for partial dentures, which were discussed earlier in this article. One distinction in the compositions, however, is the absence of carbon with the PFM compositions (Ref 131). The microstructures for two alloy systems are presented in Fig. 28.

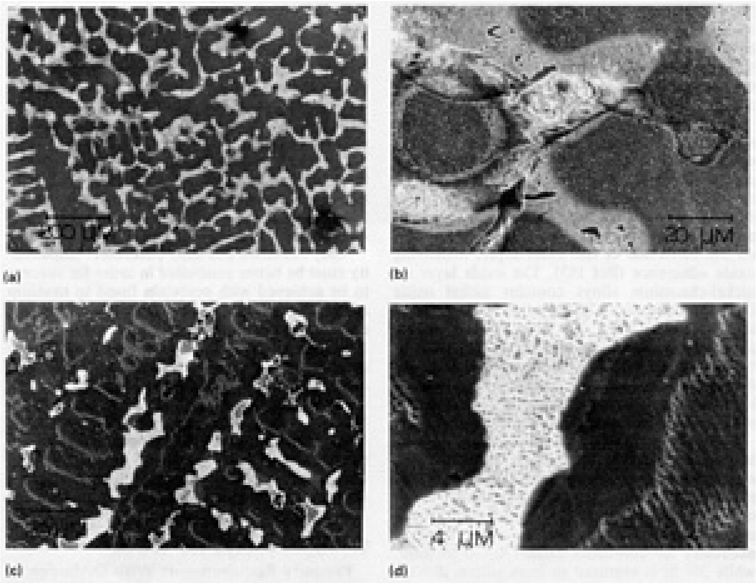

Fig. 28 SEM micrographs of etched nickel-chromium alloys for fusing with porcelain. (a) and (b) Ceramalloy. (c) and (d) Biobond

The mechanical properties of the nickel-chromium alloys are excellent for the PFM restoration. The high strengths, moduli, yield strengths, and hardnesses are used to advantage with PFM and partial dentures. Thinner alloy sections can be made from nickel-chromium alloys than from the noble metal alloys. The flexibilities of long span partial denture frameworks are only one-half those for the high gold-content alloys. Additionally, the sag resistances of the nickel-chromium alloys at the porcelain firing temperatures are superior to all of the noble metal alloys.

The bond strengths are seriously impaired by nonadherent or loosely attached oxides. A properly attached oxide is characterized by minute protrusions on the underside of the oxide layer at the alloy/oxide interface that extend into the alloy. For alloys containing additional microstructural phases, larger peg-shaped protrusions also occur on the underside of the oxide layer, improving oxide adherence (Ref 165). The oxide layer on nickel-chromium alloys contains nickel oxide (NiO) on the exterior of the oxide scale, chromium oxide (Cr_2O_3) at the interior covering the alloy, and nickel-

chromium oxide ($NiCr_2O_3$) in between. The relative amounts of the oxides depend on the chromium concentration and alloying elements in the alloy, as well as temperature, time of oxidation, and pO_2 in atmosphere.

The bond strengths between alloy and porcelain are significantly affected by minor alloying elements. The additional alloying elements of molybdenum, aluminum, silicon, boron, titanium, beryllium, and manganese also form oxides of their own. An aluminum content of 5% is necessary for aluminum oxide (Al_2O_3) to form, while 3% Si is required to form silicon dioxide (SiO_2), which increases in concentration as the alloy/oxide interface is approached. Manganese forms manganese oxide (MnO) and manganese chromite ($MnCr_2O_4$), and these are mainly concentrated at the outermost part of the oxide. Even though molybdenum oxide (MoO) volatizes above 600 °C (1110 °F), molybdenum is still found in the oxide layer close to the alloy/oxide interface with alloys containing more than 3% Mo. Beryllium, which improves the adherence of the oxide layer to the alloy, is also found concentrated near the alloy/oxide interface. Similarly, niobium is found in the oxide layer close to alloy. Tin does not diffuse throughout oxide (Ref 166).

The difficulties experienced with nickel-chromium alloys for dental applications have been at least partly related to their processing due to the use of casting techniques that had been well established for the lower-melting gold-base alloys. Because the nickel-chromium alloys melt between 1200 and 1400 °C (2190 and 2550 °F), as compared to the 850- to 1050-°C (1560- to 1922-°F) melting range for the gold-base alloys, additional casting shrinkages must be compensated for with the nickel-chromium alloys. This involves the use of phosphate- or silicate-bonded investment materials as compared to the gypsum-bonded investments used with the gold-base alloys. Technique variables with these higher-temperature investments are still being resolved. Also, the use of the gas-air torch for alloy melting, which is very popular in the dental field, cannot be used to melt nickel-chromium alloys.

Another disadvantage often cited with the harder nickel-chromium alloys as compared to the softer gold alloys is their increased finishing costs. This factor, though, should be more than offset by the decreased cost of the alloy. Even though casting accuracy may be improved with improvements in casting techniques, there may still be differences in castabilities between the different alloys. The ability to cast thin sections is a prime requirement with the dental techniques.

Other PFM Alloy Systems. The compositions of cobalt-chromium alloys for porcelain fused to metal usually have nickel, tungsten, and molybdenum as major alloying elements. Tungsten and molybdenum are high-temperature strengtheners, and therefore increase sag resistances. Tantalum and ruthenium can also be added in minor amounts. The carbon is also reduced or eliminated with PFM alloys (Ref 131). The carbon monoxide gases generated during firing of porcelain are likely to cause porosities in the interface and in porcelain. Carbon along the interface also interferes with porcelain wetting alloy during firing.

Alloy oxidation and alloy-porcelain compatibility must be better controlled in order for success to be achieved with porcelain fused to titanium alloy restorations. Titanium oxidations occurring at the currently used firing temperatures of about 1000 °C (1830 °F) must be decreased in order to achieve satisfactory alloy-porcelain bonding. The use of low firing temperature has already alloy oxidations and porcelain-alloy concentrations. Newly formulated porcelains have been used with only about one-half the coefficient of thermal expansion and with firing temperatures as low as 550 °C (1020 °F) (Ref 167). Pure titanium and Ti-6Al-4V are candidate metal substrates for PFM restorations.

Wrought Alloys for Wires

Property Requirements With Orthodontic Biomechanics. Orthodontic wires (frequently used round sizes are 0.3 to 0.7 mm, or 0.012 to 0.028 in., in diameter) constitute a large percentage of the wrought alloys used in dentistry. The wires currently in use include stainless steels, cobalt-chromium-nickel Elgiloy-type alloys, nickel-titanium Nitinol-type alloys, and β-titanium. The stainless steel and Elgiloy wires have been used extensively with conventional orthodontic biomechanics. That is, the ability to move teeth was based to a large extent on the stiffnesses of the wire appliances. Materials with high yield strength to modulus of elasticity ratios were required. The energy released from the wires during springback corresponded to areas on stress-strain curves with large slopes.

With the newer orthodontic biomechanics methodologies, however, materials with lower yield strength to modulus of elasticity ratios are desired. Here the nickel-titanium and β-titanium wires are used. The released energy under stress-strain curves with lower slopes can be large because of the greater deflections involved. The designs associated with the newer orthodontic approaches also permit greater energies to be released with time. Certified orthodontic wires comply with the property requirements of ANSI/ADA Specification No. 32, which covers base wires for orthodontics (Ref 168).

Gold-base wires are currently used on a very limited basis; in the passed, gold-base wires were used more extensively. One application, however, still relies on gold-base wires. This is for clasps on partial denture frameworks and bridges. Because of their greater ductility, clasps fabricated from gold-base alloys permit adjustments to be made with less possibility for clasp breakage. One disadvantage with this application is the need to subject the soldered bridge assembly to a heat treatment operation. The soldering leaves the gold wires in a softened condition. For this reason, base metal wires with better ductility than the cobalt-chromium frameworks but requiring no follow-up heat treatments have been used (Ref 169). Except for cast cobalt-chromium-molybdenum implant alloys, all additional implant alloys, including cobalt-chromium-tungsten, modified cobalt-chromium, and titanium and its alloys, are used in the wrought form and will be covered in the section "Implant Alloys" in this article.

Stainless Steel and Elgiloy Wires. The stainless steels used are usually the austenitic 18-8 type, although precipitation-hardening type steels have also been used. The springback of the 18-8 wires can be improved by a stress-relief heat treatment. A 400-°C (750-°F) treatment for 10 min of the as-received drawn wires generates significant improvements in springback (Ref 170). The Elgiloy wires are of the modified cobalt-chromium type. In addition to cobalt and chromium, other major alloying elements include nickel and iron. Aluminum, silicon, gallium, and copper are not added to the Elgiloy wires, as with the PFM cobalt-chromium alloys, because bonding agents with porcelain are not needed. Mechanical properties are controlled primarily through the carbon additions, which affect carbide formation. Although the operator has some control over the mechanical properties of the cobalt-chromium wires through heat treatments, the Elgiloy wires are supplied in different temper designations from soft to semiresilient to resilient.

Nitinol and β-Titanium Wires. Although Nitinol alloys have attracted interest because of their shape memory effects, this property has been used very little in orthodontics. The elasticity effect of Nitinol is its most important characteristic. Nitinol wires can almost be bent back on themselves without taking a permanent set. Even greater deformations by as much as 1.6 times can be achieved with newer superelastic nickel-titanium alloys (Ref 171). The composition of Nitinol is primarily the intermetallic compound of NiTi. The alloy is tough, resilient, and has a low modulus of elasticity. The alloy does not respond to heat treatments except for the normal homogenizing softening treatments of as-cast alloys. Cobalt is added in order to obtain critical temperatures that are useful for the shape memory effect.

Alpha-titanium (hexagonal close-packed structure) is the stable form of titanium at room temperature. By adding alloying elements to the high-temperature form of β-titanium (bcc structure), the βphase can also exist at room temperature, but in the metastable condition. The βstabilizers include molybdenum, vanadium, cobalt, tantalum, manganese, iron, chromium, nickel, cobalt, and copper. Beta-titanium is strengthened by cold working or by precipitating the phase. A variety of heat treatments can be used to alter the properties of the wires (Ref 124).

Permanent magnets are used for the fixation of dentures, bridgework, and for corrective therapy by controlling the movement of teeth. Either the attractive or repulsive forces between magnets with opposite or the same polarities have been used to advantage. For example, the repulsive forces have been used to correct cross-bite and to realign teeth. This area of dentistry is in its infancy.

The new generation of rare-earth magnets provides large magnetic forces per unit volume of material, unlike the Alnico and other previously used magnets. Disk-shaped magnets 5 to 10 mm (0.2 to 0.4 in.) in diameter and 2 mm (0.08. in.) thick that are embedded in the properly designed appliance will often provide the forces necessary in dental biomechanic treatments. Some compositions that have proved useful in dental treatments include samarium cobalt ($SmCo_5$, Sm_2Co_5) and neodymium-iron-boron ($Nd_2Fe_{17}B$).

Soldering Alloys

Composition and Applications. Gold-base and silver-base solder alloys are used for the joining of separate alloy components (Table 10). High fusing temperature base alloy solders are also used for the joining of nickel-chromium and other alloys. In many cases, the term brazing would be more appropriate, but the term is seldom used in dentistry. The gold-containing solders are used almost exclusively in bridgework because of their superior tarnish and corrosion resistance. The use of nonnoble metal containing silver-base solders is mainly limited to the joining of stainless steel and cobalt-chromium wires in orthodontic appliances because of the impermanence of the appliances.

Table 10 Compositions of some dental solders

Type	Composition, wt%						
	Au	**Pd**	**Ag**	**Cu**	**Sn**	**In**	**Zn**
Silver	. . .	. . .	52.6	22.2	7.1	. . .	14.1
Gold	45.0	. . .	20.6	28.4	4.3	. . .	2.9

The joining by soldering of small units to form a large one-piece partial denture is employed in some processing techniques. This is done to prevent framework distortions that may occur with large one-piece castings. The salvaging of large, poorly fitting castings by sectioning, repositioning, and soldering the pieces together also takes place. Both pre- and postsoldering techniques are used with PFM restorations. These imply that the soldering is carried out either prior to or after the porcelain has been baked onto the alloy substrate. Therefore, presoldering uses high fusing temperature solders, while postsoldering uses lower fusing temperature solders.

Gold-base solders are most often rated according to their fineness, that is, the gold content in weight percent related to a proportional number of units contained in 1000. Conventional gold-base crown and bridge alloys are seldom soldered together with solders having less than a 600 to 650 fineness. The soldering of gold-base wire clasps to cobalt-chromium partial dentures is another application for the higher-fineness solders. However, with the use of the low gold content crown and bridge alloys, lower-fineness solders are used. The lower-fineness solders are also occasionally used to solder the cobalt-chromium Elgiloy wires. The gold-base solders usually do not contain platinum or palladium, which increases melting temperatures. The important requirement to be satisfied during soldering is that the solders melt and flow at temperatures below the melting ranges of the parts to be joined.

The compositions of gold-base solders are largely gold-silver-copper alloys to which amounts of zinc, tin, indium, and others have been added to control melting temperatures and flow during melting. The silver-base solders are basically silver-copper-zinc alloys to which smaller amounts of tin have been added. The higher-fusing solders to be used with the high-fusing alloys are usually specially formulated for a particular alloy composition, because not all alloys have good soldering characteristics.

Microstructure of Solder-Alloy Joints. The microstructural appearance of the gold alloy-solder joints provides information as to their quality. A thin, distinct, continuous demarcation between the solder alloy and the casting alloy should exist, indicating that the solder has flown freely over the surface and that no mutual diffusion between the alloys has occurred. The junction region should be free of isolated and demarcated domains, indicative of the formation of new alloy phases. Obviously, porosity is to be avoided. However, microporosity among the phases in solder may be unavoidable. As with the cooling that occurs with all alloys, differences in the thermal expansion coefficient among phases can generate microporosity. The presence of a distinct layer of columnar dendrites within the solder starting at the solder/alloy interface and projecting into the solder bulk is assurance that there has been no tendency of the alloy surface to melt (Ref 173). The solidified solder tends to match the grain size of the parent alloy by epitaxial nucleation of the solder by the casting alloy. The microstructural characteristics of low gold content casting alloys interfaced by soldering affect the microstructural characteristics of the solidified solder (Ref 173).

Microstructurally, a silver-base solder is multiphasal. Both silver and copper-zinc rich areas occur, which is in contrast to some of the higher-fineness gold-base solders that are single phase.

Implant Alloys

Applications and Compositions. Dental implants, which are used for supporting and attaching crowns, bridges, and partial and full dentures, can be of the endosseous and subperiosteal types. The endosseous implants pass into or through the mandibular or maxillary arch bones, while the subperiosteal implants are positioned directly on top of or below the mandibular or maxillary bones, respectively. Endosseous implants are usually selected for size and type from implants already made, while the subperiosteal implants are usually custom made for the particular case. Therefore, both cast and wrought forms of implants are used. The alloys used for dental implants are similar in composition to the alloys mentioned previously for use with crowns and bridges and partial dentures. These include stainless steel, cobalt-chromium, and titanium and its alloys (Ref 22, 131).

Cast Versus Wrought Cobalt-Chromium Alloys. Castable cobalt-chromium alloys are similar to Vitallium and Haynes Stellite-21 alloys, while the wrought forms are similar to surgical Vitallium and Haynes Stellite-25 alloys. Table 8 includes compositions for some of these implant alloys. Two important distinctions exist between the cast and wrought forms (Ref 174). The casting alloy contains 5% Mo, while the wrought form contains 14 to 16% W. Molybdenum is added as a hardening agent, an oxide former, and to increase crevice and pitting corrosion resistance. Tungsten is added as a hardener and as an oxide former.

Because the wrought form can be either cold or hot worked. the alloy needs additional protection against deterioration during working. Carbides provide strengthening only up to 880 °C (1615 °F). Tungsten overcomes much of the loss in strength at higher temperatures by being a source of solid-solution strengthening above 1100 °C (2010 °F). The carbon content in the castable alloy is also higher than in the wrought form (0.35% to 0.05 to 15%). Carbide precipitations occur in the cobalt-chromium-molybdenum castable alloy, which presents a high resistance to wear. It is one of the materials of choice for applications involving moving parts.

Microstructurally, extreme differences exit between the cast and worked forms. The as-cast and annealed structures consist of distinct grain and grain boundaries interspersed with precipitated phases, similar to the micrographs shown in Fig. 27 for partial denture alloys. The cold-rolled, annealed, and hot-worked structures show a very fine grain structure oriented in the direction of working. For both structures, however, the matrix was fcc and contained carbide particles. The large chemical inhomogeneities across the surface of the alloys were indicated by the large changes in the x-ray intensities for cobalt, chromium, and molybdenum in traversing across the surfaces.

Modified cobalt-chromium alloys contain higher nickel contents. One wrought alloy included in this category is MP35N (35Co-35Ni-20Cr-10Mo). Microstructurally, the alloy takes the character of cobalt-chromium alloys. However, no carbides are formed, because carbon has not been added to the alloy.

Porous Surfaces. Alloy powders of the same composition as the implants have been sintered onto the surfaces of the implants for generating bone ingrowth to obtain better retention between the implant and the bone.

Tarnish and Corrosion Under Simulated or Accelerated Conditions

Low-Copper Amalgams. The Sn_8Hg (γ_2) phase shown in Fig. 20 is electrochemically the most active phase in conventional amalgam. Upon exposure to an electrolyte, the tin oxide (SnO)/tin couple becomes operative. The formed SnO may or may not protect the γ_2 phase from further corrosion. Depending on environmental conditions, the tin from the γ_2 phase will either be protected by a film of SnO or consumed by additional corrosion reactions.

In the case of an artificial saliva, the γ_2-tin becomes protected. This is shown in Fig. 29 on the anodic polarization curve as the current peak at about -0.7 V versus SCE, which relates in potential to the SnO/Sn couple. With increasing potential, the film protects the amalgam, as shown by the presence of a limiting or passivating current. The film will remain passivating until the potential of another redox reaction is reached that is controlling and nonpassivating. This is the situation that occurs in Cl^- solution when the corrosion potential for the amalgam approaches and surpasses the redox potential for a reaction that produces $SnOCl \cdot H_2O$.

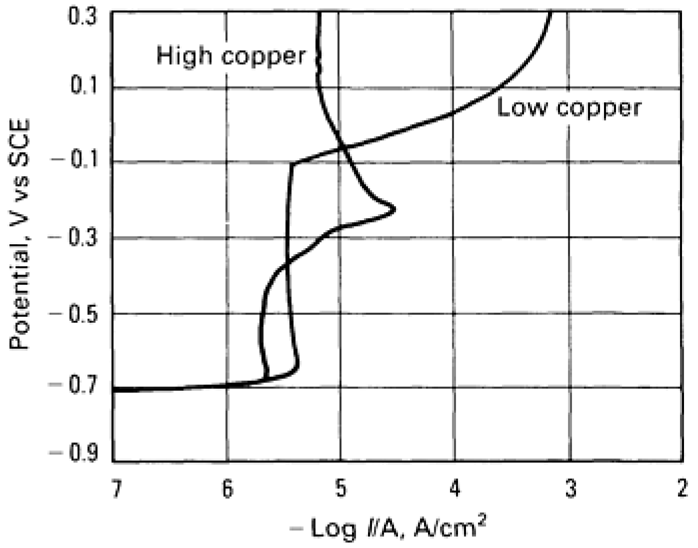

Fig. 29 Anodic polarization at 0.03 V/min of both low (Microalloy) and high (Sybraloy) copper amalgams in artificial saliva. Source: Ref 67

If this condition is satisfied, the SnO passivating film breaks down, exposing freely corroding γ_2-tin to the electrolyte. Nonprotective products of the form $SnOHCl \cdot H_2O$ precipitate. This is represented on the polarization curve in Fig. 29 as the sharp increase in current at about -0.1 V. Because the interconnection of the γ_2 phase, the interior γ_2 can also become corroded. Figure 30 shows the devastating effect that corrosion of the γ_2 phase has on the microstructure of a conventional amalgam, while Fig. 31 shows typical tin-containing products that precipitate on the surface.

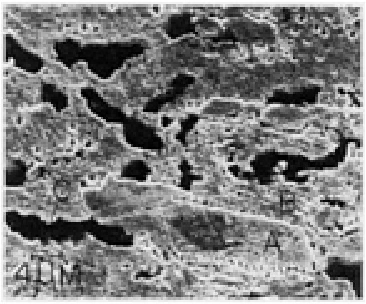

Fig. 30 SEM micrograph of corroded (10 μA/cm^2) low-copper amalgam (New True Dentalloy) in 0.2% NaCl after removal of corrosion products by ultrasonics. A, alloy particles; B, matrix; C, regions formerly occupied by γ_2 phase

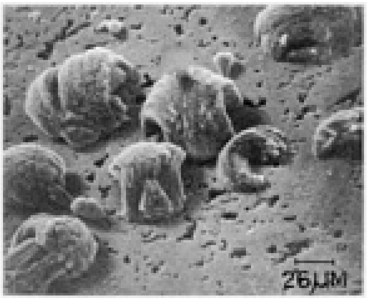

Fig. 31 SEM micrograph of low-copper amalgam (New True Dentalloy) after immersion in artificial saliva. The clumps of corrosion products contain tin. Source: Ref 175

High-Copper Amalgams. Corrosion of high-copper amalgams by γ_2-phase corrosion will not occur, because of its almost complete absence from the microstructure. Although possessing better corrosion resistance than the γ_2-phase, the Cu_6Sn_5 (η') phase will be the least resistant phase in the microstructure (Fig. 21, 22). Upon exposure to solution, any corridable tin within the material first forms a protective SnO film indicated on the anodic polarization curve in Fig. 29 as the small current peak at about -0.7 V. Upon attaining a steady-state corrosion potential in chloride solution, high-copper amalgam is likely to surpass redox potentials for couples of $CuCl_2$/Cu, $Cu(OH)_2$, Cu_2O/Cu, and $CuCl_2\cdot 3Cu(OH)_2$/Cu. Under these conditions, both soluble and insoluble corrosion products will form. This is indicated on the polarization curve as a small anodic current peak at about -0.25 V.

Microstructurally, if the copper from the η' phase becomes exhausted by corrosion, copper corrosion from the silver-copper and γ particles may also follow. Freed by copper corrosion, tin also becomes corroded. Corrosion of the γ_1-tin decreases the stability of the γ_1 phase, which is likely to be transformed into the β_1 phase. Unlike low-copper amalgam, the interior of high-copper amalgam is not likely to become affected by corrosion, because of the noninterconnection of any of the phases. Figure 32 shows a corroded high-copper dispersed-phase amalgam, emphasizing the reaction zones of the η' phase, the interior of the silver-copper particles, the γ particles, and the matrix.

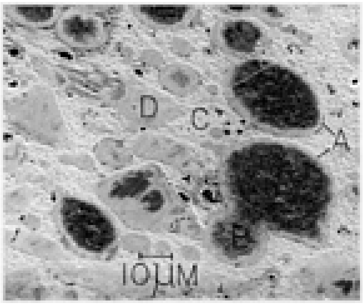

Fig. 32 SEM micrograph of corroded (5 $\mu A/cm^2/d$) high-copper amalgam (cluster) in 0.2% NaCl solution. Note the definition of the η' rings(A), Ag-Cu particles (B), matrix (C), and η' particles (D).

Tarnish of Gold Alloys. Because tarnish is by definition the surface discoloration of a metallic material by the formation of a thin film of oxide or corrosion product, the quantification of dental alloy tarnish by assessing color changes on surfaces is most appropriate. By determining the color of an alloy before and after exposure to a test solution, the degree of discoloration can be obtained by quantitative colorimetry techniques, which are described in Ref 105 and 144, 145, 146, 147, 148, 149 The use of quantitative colorimetry in conjunction with SIMS for determining the effects of alloy nobility (in atomic percent) and sulfide concentration on color changes in gold crown and bridge alloys is detailed in Ref 176.

Effect of Microstructure on Tarnishing Behavior. The devastating effect of microgalvanic coupling on tarnishing behavior is shown by a comparison of solid-solution annealed and as-cast structures (Fig. 33). The as-cast alloys, composed of two-phase structures, consistently showed greater color change or tarnish (Ref 146).

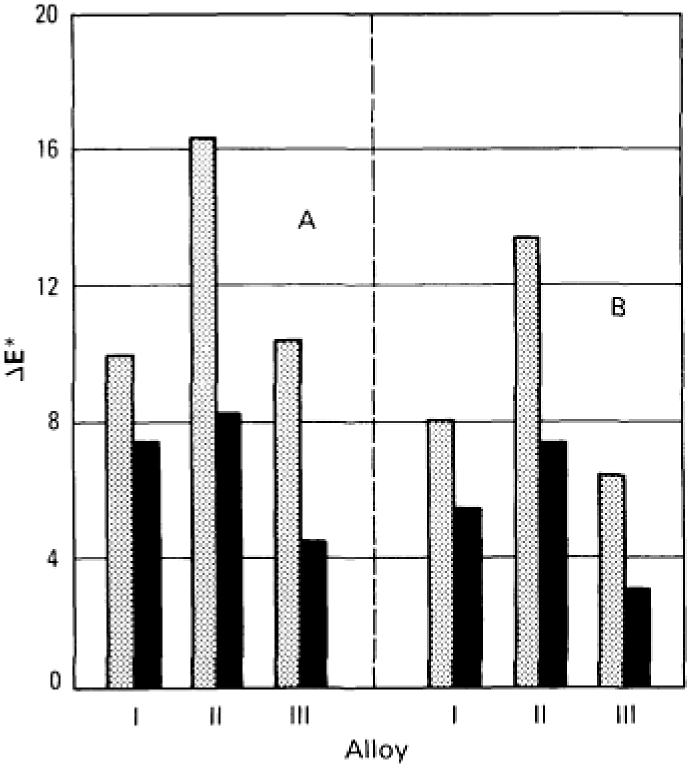

Fig. 33 Color change vector ΔE* for three low-gold alloys (I, Miracast; II, Sunrise; III, Tiffany) in both the as-cast (left bar for each alloy) and solutionized at 750 °C (1380 °F) (right bar for each alloy) conditions after exposure for 3 days to artificial saliva (A) or 0.5% Na_2S solution (B). Source: Ref 146

Single-phase as-cast gold-silver-copper alloys with gold contents between 50 to 84 wt% were observed microstructurally to tarnish in Na_2S solutions by localized microgalvanic cells. The characteristics of the various tarnished surfaces included a uniformly speckled appearance, dendritic attack, matrix attack, grain-boundary dependent attack, and grain-boundary attack. Silver-rich areas discolored preferentially because of the operation of the silver-rich areas as anodes and the surrounding copper-rich areas as cathodes. The uniformly speckled appearance occurred with high-silver low-copper contents, while the grain orientation dependent appearance occurred with low-silver high-copper contents. The dendritic and matrix attack occurred with alloys containing intermediate silver and copper contents (Ref 96).

For gold-silver-copper-palladium alloys with gold contents between 35 and 73 wt%, the tarnishability in oxygenated 2% Na_2S is shown to be affected by altering the microstructure through heat treatment. Tarnishing occurred on multiphase structures annealed at 500 °C (930 °F), but did not occur on single-phase structures annealed at 700 °C (1290 °F). Silver, copper, and palladium-rich phases were precipitated. Some alloys, though, showed only silver- and copper-rich phases. In these cases, the palladium tended to follow the copper-rich phase. Splitting of the matrix into thin lamellae of alternating silver and copper enrichments occurred. The silver-rich phases in all materials were attacked by the sulfide and were responsible for the tarnish. Age hardening by AuCu(I)-ordered precipitates increased the tendency of the silver-rich lamellae to tarnish (Ref 177).

In sulfide solutions, silver sulfide (Ag_2S) is the principle product of tarnish, although copper sulfides (Cu_2S and CuS) also form. These products are produced by the operation of microgalvanic cells set up between silver-rich and copper-rich lamellae. The addition of palladium to gold-silver-copper alloys considerably reduces the rate of tarnishing by slowing down the formation of a layer of silver and copper sulfides on the surface. This has been shown to be due to the enrichment of palladium and gold on the surface of the alloy when exposed to the atmosphere prior to sulfide exposure (Ref 178). The rate of diffusion from the bulk to the surface is hindered by the palladium enrichment. The active sites on the alloy surface for the sulfidation reaction are selectively blocked by the palladium atoms (Ref 178).

Figure 26 presents chemically etched microstructures for a number of different casting alloys. All structures are multiphase, except for Sterngold 20 and Midas. After the surfaces were repolished and exposed for 3 days to a 0.016% Na_2S solution with a rotating tarnish tester (15 s exposure/min), the surfaces were again examined by scanning electron

microscopy (SEM). Some of the results are presented in Fig. 34, which shows that tarnishing for all alloys took the form of dark patches over the alloy surfaces.

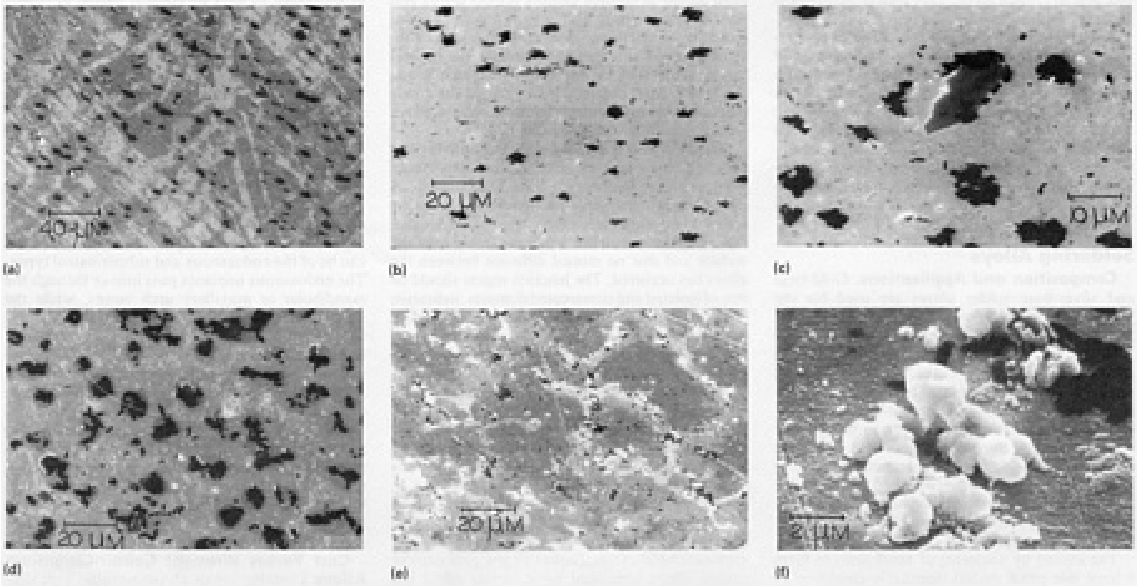

Fig. 34 SEM micrographs of low-gold alloys after 72 h of alternate-immersion tarnishing in artificial saliva containing 0.016% Na_2S. (a) Sterngold 20. (b) Tiffany. (c) Pentron 20. (d) Sunrise. (e) and (f) Econocast. See Table 6 for chemical compositions. Source: Ref 176

Effect of the Silver/Copper Ratio. The silver/copper ratio is an important aspect in affecting the tarnish and corrosion resistance of gold dental alloys. A comparison of Midacast to Neycast III and Miracast (see Table 6) shows that all three alloys have about the same nobility but vastly different Ag/Cu ratios (based on weight percent), ranging from 41/7.4 for Midacast to 10.3/37.9 and 9.8/37.7 for Neycast and Miracast, respectively (Ref 177). A comparison of their polarization behavior in a sulfide solution shows the Midacast exhibits increases in current density up to 10 $\mu A/cm^2$ at -0.3 V, while Neycast III and Miracast exhibit a current density of ~1 $\mu A/cm^2$ extending to positive potentials. Therefore, high silver contents relative to low copper contents in low gold alloys can have detrimental effects upon tarnishing and corrosion. For Forticast (the composition also given in Table 6) unacceptable levels of tarnish would occur if the silver/copper ratio were changed (Ref 158). For some low-gold alloys, the best resistance to tarnishing has been obtained by using ratios between 1.2 and 1.4 and a palladium content of 9 wt%.

Effect of the Palladium/Gold Ratio. Increasing the palladium content in gold alloys increases the tarnish resistance. However, in gold-silver-copper-palladium alloys, this effect is greater. The palladium/gold ratio is just as important as the silver/copper ratio. In gold-silver-copper alloys without palladium, the degree of tarnish (subjective test: 0 = least and 8 = most) was evaluated to be between 6.5 and 8 for all silver/copper ratios (1:3, 1:2, 2:3, 1:1, 3:2, 2:1, 3:1) (Ref 101). However, in alloys having palladium/gold ratios of 1:12, the degree of tarnish diminished to between 2 and 3.

Tarnishing and Corrosion Compared. Figure 35 shows reflection loss versus nobility and weight loss versus nobility for the same 15 gold alloys. Tarnishing was by immersion for 3 days in 0.1 *M* Na_2S, while corrosion was by immersion in 0.1 *M* lactic acid. As is evident, a number of alloys that appear not to have been affected by corrosion are, however, largely affected by tarnishing (Ref 179).

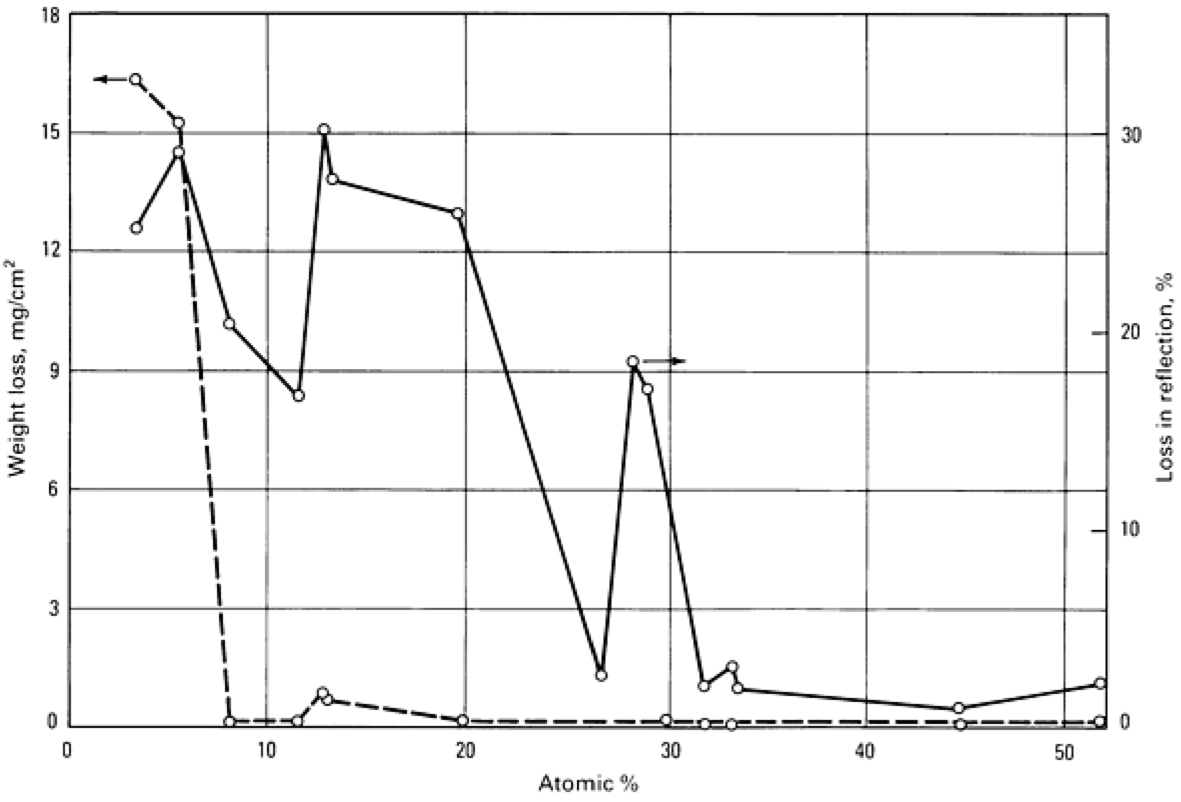

Fig. 35 Effect of nobility (in atomic percent) on tarnish (percent loss in reflection after 3 days in 0.1% Na_2S) and corrosion (weight loss after 7 days in aerated 0.1 *M* lactic acid plus 0.1 M NaCl at 37 °C or 99 °F) of 15 gold alloys. Source: Ref 179

Corrosion of Gold Alloys. Electrochemical polarization has been applied to the corrosion evaluation of gold dental alloys. High nobility alloys exhibited low current densities over a wide range in potentials in Ringer's solution, but low nobility alloys exhibited increased current densities and decreased breakdown potentials (Ref 180). Very small current peaks on the anodic polarization curves for some gold alloys in artificial saliva were detected and interpreted to be due to the dissolution of alloying components (Ref 181).

A comparison of the anodic polarization of noble alloys in artificial saliva with and without sulfide indicated that without sulfide the electrochemistry is governed mainly by chloride ions. The alloys passivate in a state with very low current densities, which makes detection of differences among the alloys difficult. With sulfide added to the artificial saliva, a preferential sulfidation of the less noble alloy component is induced. The sulfidation is characterized by a critical potential and limiting current density, both of which may be dependent on composition (Ref 182).

The corrosion susceptibilities for silver and copper in various gold alloys were quantified by an analysis of both forward and reverse polarization scans (Ref 183). Both silver and copper demonstrated characteristic current peaks during either oxidation or reduction. The heights of the current peaks were taken to be a measure of the amount of corrodible silver and copper in the alloys. In a similar technique, the integrated current from the polarization curves within a potential range of -0.3 V versus SCE to +0.3 V was taken to be a measure for the corrodible species (Ref 184). Figure 36 presents a rank ordering of eight as-cast gold alloys in regard to nobility plotted versus their integrated anodic currents, while Fig. 37 shows the effect of heat treatment state on the polarization corrosion index for a low gold content alloy.

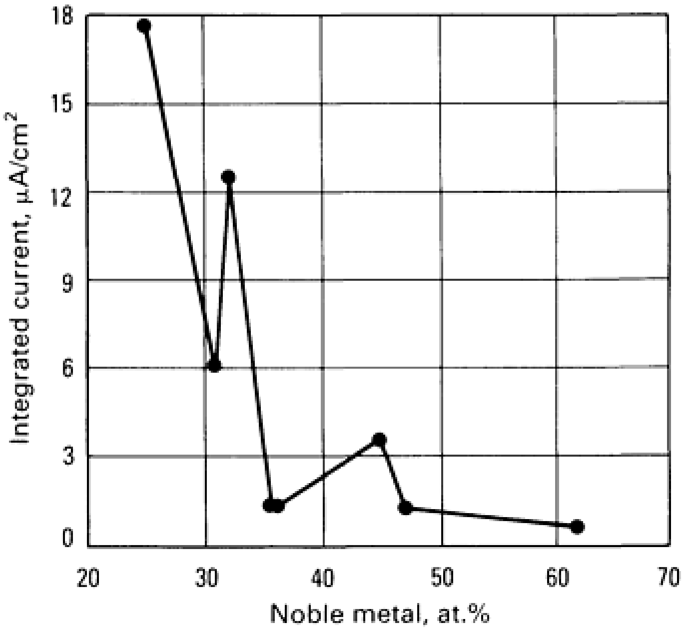

Fig. 36 Integrated anodic currents between -0.3 V versus SCE and +0.3 V (at 0.06 V/min) for eight gold alloys in deaerated 1% NaCl plotted against the atomic nobility. Source: Ref 146

Silver-Palladium Alloys. Silver is prone to tarnishing by sulfur and is prone to corrosion by chloride. The addition of palladium to silver generates alloys with much better resistance to tarnishing and silver corrosion. In 1/7 diluted Ringer's solution and 0.1% NaCl, alloys with more than 40% Pd showed passive anodic polarization behavior (Ref 185). In sulfur-saturated air, the amount of sulfur deposited onto the surfaces of silver-palladium alloys was minimal for compositions with ≥40 wt% Pd (Ref 182). In artificial saliva, two transitions in the corrosion currents occurred with palladium content.

The first occurred at about 22% Pd, where the current decreased from 6 to 1 μA. The second transition occurred at about 29% Pd, where the current decreased to about 0.4 μA and then remained fairly constant throughout the rest of the compositional range (Ref 186). Figure 38 shows the color range vectors for the pure metals and alloys from the Ag-Pd system after tarnishing in artificial saliva with 0.5% Na_2S. Compositions 50Pd-50Ag and 75Pd-25Ag showed the best tarnish resistance (Ref 187).

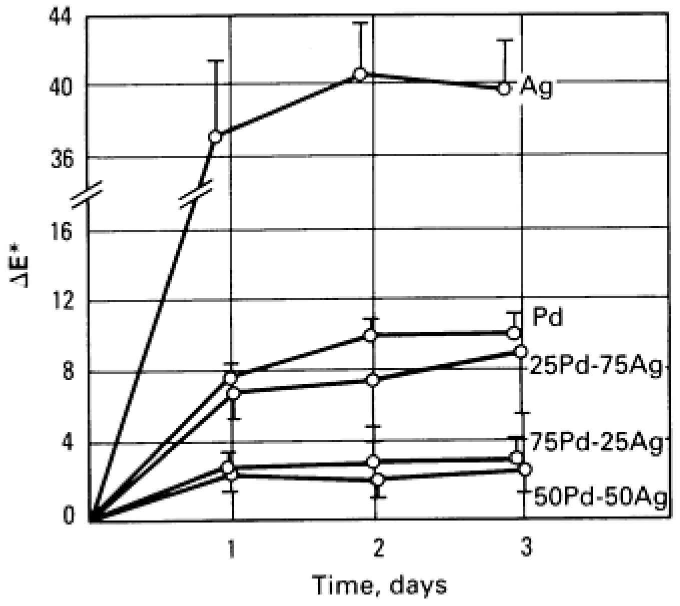

Fig. 38 Color change vector ΔE* for pure silver, palladium, and three Ag-Pd binary compositions after exposure to Na_2S solutions. Source: Ref 187

Corrosion behavior and tarnishing behavior usually must be viewed independently. That is, corrosion is not an indicator for tarnishing, and vise versa. Alloy nobility dominates corrosion behavior, while alloy nobility, composition and microstructure, in conjunction with environment, influence tarnishing behavior.

Microstructurally, the silver-palladium alloys tarnish by chlorides and/or sulfides becoming deposited over the silver-rich matrix, while the palladium-rich precipitates display resistance to chlorides and sulfides. With forward and reverse scan polarization, the amounts of corrodible silver and copper in silver-palladium alloys were characterized by comparing the relative current magnitudes for reduction peaks. Microstructurally, the alloys were composed of a corrosion-resistant copper- and palladium-rich phase and a nonresistant silver-rich phase. Increased tarnish and corrosion of the silver-rich phase component, occurred by microgalvanic coupling (Ref 188). Manipulation of the microstructural features through heat treatments produced structures with varying proportions of the tarnish-resistant and tarnish-prone phases. Age hardening increased the proportion of the tarnish- and corrosion-prone phases (Ref 189, 190).

High-Palladium Ceramic Alloys. Alloys with up to 80%Pd and additions of copper, gallium, tin, indium, gold, and others were shown to exhibit good saline corrosion resistance in the potential range and Cl^- ion concentration associated with oral use. Anodic polarization showed passive behavior until breakdown occurred, which was well above potential magnitudes occurring intraorally (Ref 163). For similar compositions and palladium-base compositions containing cobalt, spontaneous passivation or active-passive behavior occurred in chloride solutions. Differences among the polarization profiles for the various palladium-base alloys were detected, but any differences corresponded to high potentials generally above the biodental range (Ref 161).

The effects of adding copper and gallium to palladium were determined by modeling alloy composition and corresponding electrochemical behavior to a linear regression and equation. The resultant coefficients accounted for the individual elemental effects on corrosion potential and anodic Tafel constants. Elements that increased the nobility of the corrosion potential also increased the rate of corrosion. This was attributed to anodic protection occurring at the surface of the alloys (Ref 162).

Nickel Chromium Alloys. The tarnish resistance and corrosion resistance of these alloys result from balancing the composition with regard to the passivating elements chromium, molybdenum, manganese, and silicon. Alloys containing increased amounts of molybdenum and manganese exhibited increased passivation. Increasing the chromium content too much (above 20%) can precipitate an additional phase and alter the corrosion resistance. By using polarization methods, 3 different behaviors were observed with 12 nickel-chromium alloys with varying compositions in deaerated and aerated artificial saliva (Ref 191). Some alloys were constantly passive, others were either active/passive or passive according to the aeration condition of the electrolyte, and still others (<16% Cr without molybdenum) were constantly active and corroding.

Corrosion potentials for nickel-chromium alloys in artificial saliva were low, ranging between about -0.2 V and -0.8 V versus SCE. Breakdown potentials varied, depending on composition. For alloys with less than 16% Cr and no molybdenum, breakdown potentials as low as -0.2 V occurred. For compositions with higher chromium contents and with molybdenum and various manganese contents, breakdown potentials as high as +0.6 V also occurred.

Pitting attack occurs with these alloys because the rely on protective surface oxide films for imparting protection. From electrochemical and immersion tests, the resistance of nickel-chromium alloys to pitting attack wa found to be good in solutions with Cl^- concentrations equivalent to that found in saliva. Only at higher Cl^- concentrations are pitting and tarnishing likely to occur (Ref 192).

Cobalt-Chromium Alloys. Compared to the nickel-chromium alloys, the cobalt-chromium alloys for partial denture and implant prosthesis exhibit superior tarnish and corrosion resistance. Cobalt-chromium alloys exhibit passive behavior to potentials of at least +0.5 V (Ref 70, 193), but the nickel-chromium alloys exhibit much greater variations in behavior. For some of the nickel-chromium alloys, breakdown potentials can be as low as -0.2 V (Ref 191, 193). In spite of the excellent corrosion resistance of cobalt-chromium alloys, allergic reactions to cobalt, chromium, and nickel contained in appliances made from these alloys are know to have occurred (see the section "Allergic Hypersensitive Reactions" in this article).

Titanium Alloys. Titanium and titanium alloys, like the cobalt-chromium alloys, have proved to be resistant to tarnish and corrosion. The anodic polarization for pure titanium and its alloys indicates passivities over at least several volts in overvoltage (Ref 70, 193). This demonstrates the tenacity and protectiveness of the titanium oxide films formed on these materials.

With regard to the newer casting titanium alloys for crown and bridgework and partial dentures, good corrosion resistance is still preserved (Ref 141). Concerns must be raised because the casting alloys contain higher percentages of alloying elements, with the potential for elucidating diminished chemical stabilities.

One wrought titanium alloy, Nitinol, containing about 50% Ni and 50% Ti, does not exhibit the same high corrosion resistance as alloys with 80 to 90% Ti, and higher. Nitinol is covered in the following section.

Wrought Orthodontic Wires. A comparison of their anodic polarization curves (Fig. 39) shows that both β-titanium and Elgiloy exhibit resistance to corrosion in artificial saliva. No breakdown in passivity occurred within the potential ranges employed (+0.8 V). With Nitinol and stainless steel wires, breakdown occurred at +0.2 and 0.05 V, respectively. Nitinol and stainless steel also exhibited current increases upon potential reversals at +0.8 V, an indication of the susceptibility to pitting corrosion. Breakdown potentials differed by as much as 0.6 V between different brands of stainless steel wires. Variations in the polarization characteristics of stainless steel have been related to microstructure (Ref 70) and to surface preparation and finish (Ref 71). Microstructurally, the Nitinol wires were observed to suffer pitting attack after polarization tests (Ref 195).

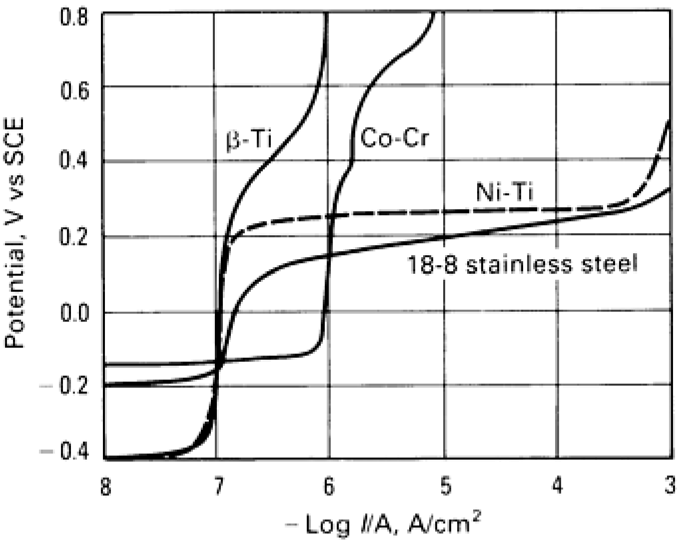

Fig. 39 Anodic polarization at 0.03 V/min of four orthodontic wires in artificial saliva. Source: Ref 194

Silver and Gold Solders. A corroded silver soldered-stainless steel joint is shown in Fig. 40. Microstructurally, silver solders are composed of two phases: silver-and copper-zinc rich segregations (Ref 196). The copper-zinc regions are the least resistant to corrosion. These solders corrode by microgalvanic coupling, either by cells set up between the two microstructural phases or between solder and the parts they join. Figure 41 shows the copper-zinc phase of a silver solder attached by corrosion. In addition to the release of copper and zinc into the surrounding environment, metallic ions from the wires themselves were also shown to be leached into the wires (Ref 25). The leaching of nickel and chromium from stainless steel wires occured with greater intensity than from the wires of the cobalt-chromium type.

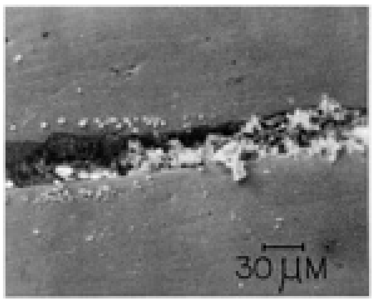

Fig. 40 SEM micrograph of a corroded stainless steel-silver soldered joint after immersion in a 1% H_2O_2 solution. Source: Ref 196

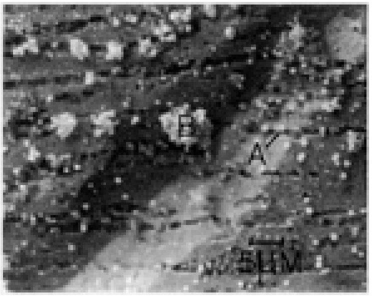

Fig. 41 SEM micrograph of a corroded silver solder in 1% NaCl (held at -0.05 V versus SCE) showing the destruction of the copper-zinc-rich phase (A) and the accumulation of products (B) that contain copper, zinc,

and chlorine. Source: Ref 196

Figure 42 shows the polarization curves for both silver and gold (450 fine) solders. The silver solder is characterized by active behavior, as indicated by the low corrosion potential of -1.2 V versus SCE in 0.16 *M*NaCl on the anodic polarization traverse and the numerous current peaks related to redox reactions with the elements constituting the solder. Therefore, zinc, tin, copper, and even silver products are likely to be precipitated or become dissolved in solution.

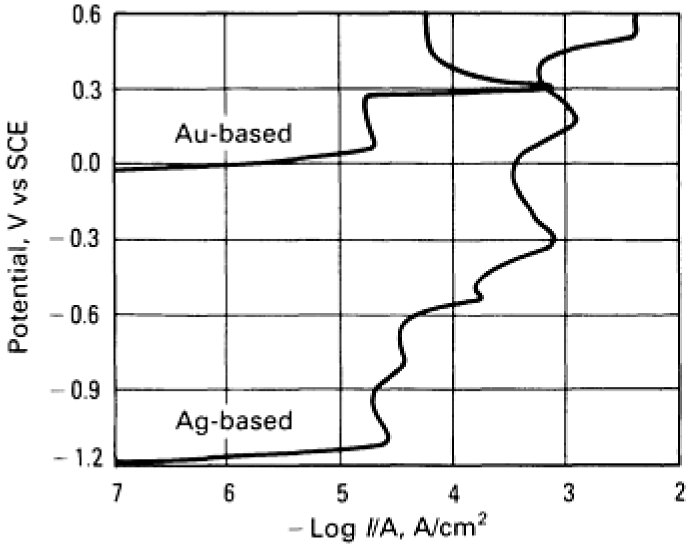

Fig. 42 Anodic polarization at 0.03 V/min of silver and gold (450 fine) solders in 1% NaCl solution. Source: Ref 196

The polarization curve for gold solder indicates intense activity by the sharp current density peak at +0.25 V. Because the solder contains silver, copper, and zinc, in addition to gold, this peak is probably due to the corrosion of one of these elements. Figure 43 shows the gold solder after the polarization test. Corrosion has delineated the basic microstructure of the solder alloy. Chlorine was detected with the white appearing phase.

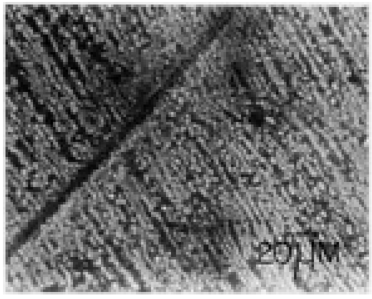

Fig. 43 SEM micrograph of a corroded (polarized to +0.5 V versus SCE) gold solder (450 solder) in 1% NaCl. The light areas contain chlorine. Source: Ref 196

Silver-Indium Alloys. These alloys rely on the unusual properties of indium oxide for providing tarnish and corrosion control. Small amounts of noble metals, such as palladium, may also be added in an attempt to improve corrosion resistance. Anodic polarization of a silver-indium alloy in artificial saliva indicated only a very narrow potential range of about 0.1 V of reduced current densities. The tarnish resistance of these alloys appears to be acceptable, but the long-term corrosion resistance has yet to be established (Ref 197).

Copper-Aluminum Alloys. A comparison of the released copper in human saliva from a dental copper-aluminum alloy to that from a high-copper amalgam is shown in Fig. 44. The amalgam released more copper over a 45-day interval. No aluminum, iron, manganese, or nickel was detected. Figures 45(a) to (c) show micrographs from an *in vivo* restoration of various magnifications. Large amounts of organic matter were adsorbed onto the surface, as well as light powdery corrosion products composed of copper oxides (Ref 68).

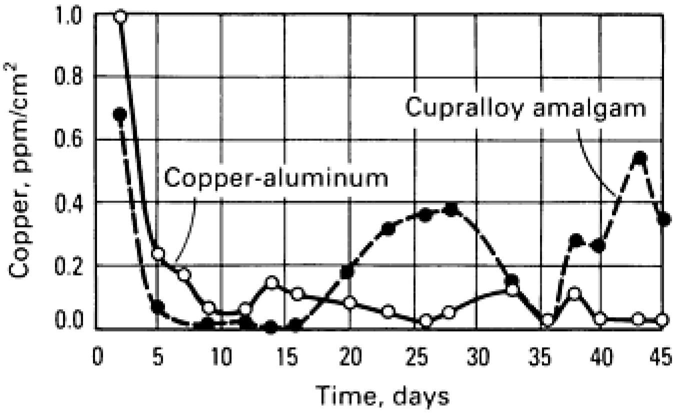

Fig. 44 Released copper into human saliva from a copper-aluminum crown and bridge alloy (MS) and a high-copper amalgam (Cupralloy) plotted against time for up to 45 days. Source: Ref 68

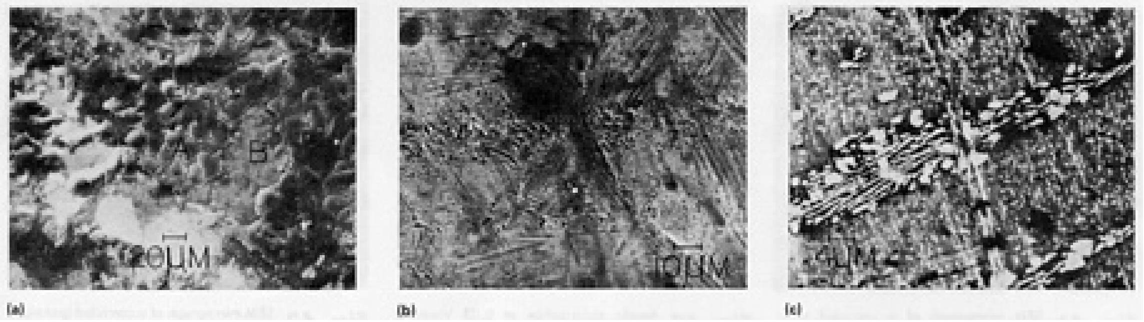

Fig. 45 SEM micrographs of the copper-aluminum restoration shown in Fig. 18 at higher magnifications. In (a), both accumulated plaque (A) and corrosion products (B) occur. (b) Higher-magnification view of the areas identified by (B) contain copper. The light-appearing areas are probably copper oxides. (c) Still higher magnification of the products shown in (b). Here the copper oxides are deposited over the dark copper-rich microstructural phase. Source: Ref 68

Rare-Earth Permanent Magnets. The anodic polarization of $SmCo_5$, Sm_2Co_{17}, and $Nd_2Fe_{14}B$ in artificial saliva indicates active behavior (Fig. 46). Additional *in vitro* and *in vivo* tests have indicated their poor chemical stability. Scanning electron microscopy, energy dispersive spectroscopy, and secondary ion mass spectroscopy identified some of the products to be oxides and chlorides of samarium, in the case of samarium-cobalt materials, and of iron and neodymium with the neodymium-iron-boron materials. Figure 47 shows an $Nd_2Fe_{17}B$ orthodontic bracket after several weeks of *in vivo* use. Abundant amounts of corrosion products occurred. In their present state, these materials are unacceptable for routine bioapplications. However, because of their extreme usefulness in providing relatively large magnetic forces from small volumes of material, special efforts are being made to apply surface coating technologies to the rare-earth magnets (Ref 198).

Corrosion of Emission-Control Equipment

William J. Gilbert and Robert John Chironna, Croll-Reynolds Company, Inc.

Introduction

CORROSION PROBLEMS and material selection for emission-control equipment can be difficult because of the varied corrosive compounds present and the severe environments encountered. Therefore, a number of the more common emission-control applications will be discussed. More detailed information on the applications is available in the references cited at the end of this article.

Flue Gas Desulfurization

By far the most common cleaning application for flue gases is flue gas desulfurization (FGD). This section will discuss the selection of materials of construction for FGD systems. More information on corrosion in FGD systems is available in the section "Corrosion of Flue Gas Desulfurization Systems" of the article "Corrosion in Fossil Fuel Power Plants" in this Volume.

These systems came into being in the late 1960s and early 1970s because of the tightening of restrictions on the release of sulfur emissions. The oil shortage of the mid-1970s and subsequent oil price increases led to the reuse of coal in new and renovated power plants. In virtually all cases, this meant the potential for increased sulfur emissions. Many more FGD systems were needed.

Fuel gas desulfurization systems typically use wet scrubbing units with lime or limestone slurries for sulfur dioxide (SO_2) absorption. Initially, it was thought that the relatively mild pH and temperature conditions found within most of these systems would not present a significant corrosion problem. This was soon found not to be the case. The fact that the FGD system could constitute up to 25% of the total capital and operating expenses of the power plant made it imperative to determine the reasons behind the failure of the material.

Environment. The gases encountered by the FGD system are hot and contain SO_2 at significant levels, some sulfur trioxide (SO_3) as a result of the oxidation of SO_2 at high temperatures, and fly ash. Initially, these gases may be sent to a dry-dust collector, such as an electrostatic precipitator of fabric filter baghouse, for fly ash removal. The gases typically enter a wet scrubber (venturi with separator) and are quenched as SO_2 is absorbed. The components that often have the severest problems, however, are the outlet duct and stack. Here the condensates are more acidic, the gases are highly oxygenated, and the presence of chlorides and fluorides, can cause serious corrosion problems. Nevertheless, throughout the entire system, corrosion can occur to various degrees and because of various factors.

Corrosion Factors. Four basic factors affect the severity and type of corrosion that occurs. They are discussed below.

pH. The result of the reactions that take place within the scrubber is a slurry with a typical pH of 4 to 5. This is desirable, because it allows for good absorption of SO_2 and is acidic enough to reduce scale formation. Local pH values as low as 1 may exist from the concentration of chlorides entering the makeup liquid with contributions from fluorides. The low-pH conditions with the presence of chlorides and fluorides limit the use of carbon steels, stainless steels, and a number of higher-nickel alloys (Fig. 1).

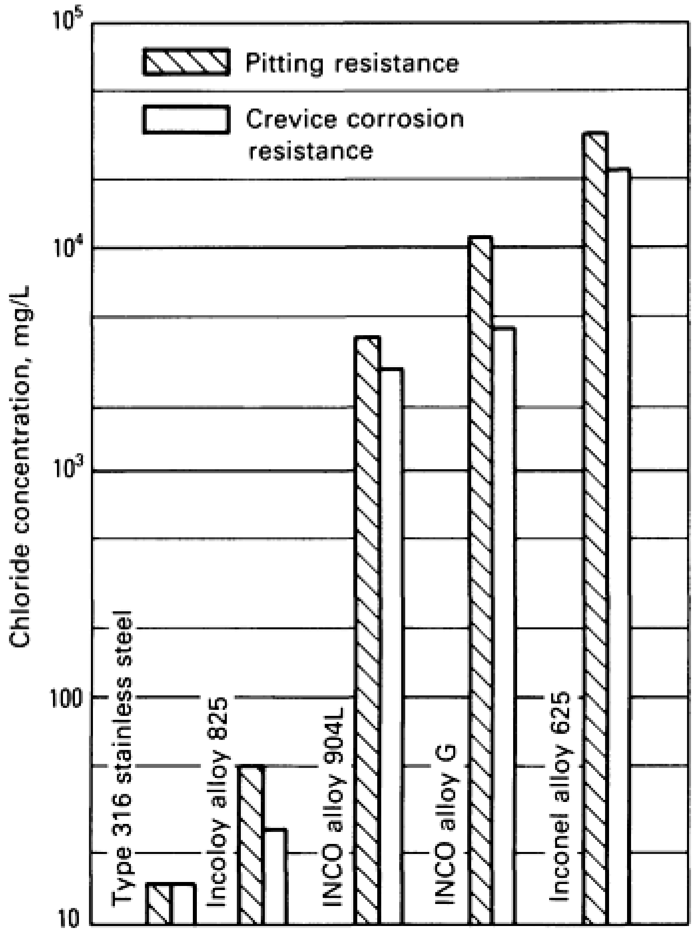

Fig. 1 Minimum levels of chloride that cause pitting and crevice corrosion in 30 days in SO_2-saturated chloride solutions at 80 °C (175 °F). Source: Ref 1

Gas Saturation. The dry flue gas is not severely corrosive. However, when the gas reaches its dew point, sulfuric (H_2SO_4) and sulfurous (H_2SO_3) acids can form. In addition, hydrochloric acid (HCl) is produced because of the presence of hydrogen chloride (formed at the elevated temperatures of combustion) plus the condensing water vapor. Again, significant problems arise from the use of carbon or stainless steels.

Temperature. The problems caused by temperature excursions are primarily related to the lessening of the corrosion-resistant properties of synthetic coatings, fiberglass-reinforced plastics (FRP), and thermoplastics, possibly to the point of complete destruction at high enough temperatures. This affects metals to a lesser extent, but can make a bordering problem a serious one.

Erosion generally occurs as a result of fly ash within the gas impacting on a surface in a relatively dry area of the system or the liquid slurry impinging upon a wetted surface. In either case, areas susceptible to corrosion attack are produced.

General Materials Selection. An easily overlooked but critical aspect of materials selection is the ability of the manufacturer to construct the equipment properly with correct fabrication techniques. In particular, with regard to the use of high-nickel alloys, the welding recommendations of alloy producers should be precisely followed to maintain the corrosion resistance of the materials (Ref 2). This is of course true for any type of fabrication. The most careful materials selection process can be negated by poor fabrication practices.

Metals. Where pH is neutral or higher, austenitic stainless steels (AISI types 304, 316, and 317, L grades preferred) perform well even at elevated temperatures. If pH is as low as 4 and chloride content is low (less than 100 ppm) but temperatures are above approximately 65 °C (150 °F) then Incoloy 825, Inconel 625, Hastelloy G-3, and alloy 904L

(UNS N08904) or their equivalents are usually acceptable. Table 1 lists compositions of alloys commonly used in FGD systems.

Table 1 Compositions of some alloys used in FGD systems

Alloy	Composition, %[a]						
	C	**Fe**	**Ni**	**Cr**	**Mo**	**Mn**	**Others**
Type 304L	0.03 max	bal[b]	10.0	19.0	. . .	2.0 max	0.045 max P, 0.03 max S,and 1.00 max Si
Type 316L	0.03 max	bal	12.0	17.0	2.5	2.0 max	1.00 max Si 0.045 max P, and 0.03 max S
Type 317L	0.03 max	bal	13.0	19.0	3.5	2.0 max	1.00 max Si, 0.045 max P, and 0.03 max S
Inconel alloy 625	0.10 max	5.0 max	bal	21.5	9.0	0.50 max	0.40 max Al, 0.40 max Ti, 3.65 Nb, 0.015 max P, 0.015 max S, and 0.50 max Si
Incoloy alloy 825	0.05	bal	42.0	21.5	3.0	1.0 max	0.8 Ti, 0.5 max Si, 0.2 max Al, 2.25 Cu, and 0.03 max S
INCO alloy G	0.05 max	19.5	bal	22.25	6.5	1.5	1.0 max Si, 2.125 Nb, 2.5 max Co, 2.0 Cu, 1.0 max W, and 0.04 max P
INCO alloy G-3	0.15 max	19.5	bal	22.25	7.0	1.0 max	5.0 Co, 2.0 Cu 0.04 max P, 1.0 max Si, 0.03 max S, 1.5 max W, and 0.05 max Nb + Ta
INCO alloy C-276	0.02 max	5.5	bal	15.5	16.0	1.0 max	2.5 max Co, 0.03 max P, 0.03 max S, 0.08 max Si, and 0.35 max V
INCO alloy	0.02	bal	25.5	21.0	4.5	2.0	1.5 Cu 1.0 max Si, 0.045 max P, and 0.035 max S

(a) Nominal composition unless otherwise specified.

(b) bal, balance

When chloride content is up to 0.1% and pH approaches 2, only Hastelloys C-276, G, and G-3, and Inconel 625 can be successfully used. The other alloys mentioned above would be subjected to pitting and crevice corrosion. If a region is encountered with pH as low as 1 and chloride content above 0.1%, one of the only successful alloys acceptable is reported to be Hastelloy C-276 or its equivalent. In terms of metals selection, the higher the molybdenum content in an alloy, the more severe the corrosive environment it can withstand in the FGD system (Ref 3).

Nonmetals. Fiberglass-reinforced plastics can be used in almost any application in which temperatures do not exceed 120 °C (250 °F) (preferably 95 °C, or 205 °F), regardless of whether there are high chlorides or low pHs. The best choices would be premium grades of vinyl-ester and polyester resins. Polypropylene(PP), chlorinated polyvinyl chloride (CPVC), and other thermoplastics can be used in such applications as mist elimination, in which temperatures are suitably low, for example, 80 °C (175 °F) for PP. Rubber linings can also be used where temperatures are suitable and mechanical damage can be avoided.

Waste Incineration

In a number of ways, the problems associated with materials for incinerator off-gas treatment equipment are similar to those used for FGD systems. Depending on the wastes being burned, however, significantly higher gas temperatures as well as more varied and more highly corrosive compounds may be encountered. Materials selection for waste incineration parallels that for FGD systems to some extent, but can often be more demanding.

The importance of incineration for the treatment of domestic and industrial wastes has increased as the availability of sanitary landfills has lessened and their costs have escalated. At the same time, environmental safety regulations have limited the use of deep below-ground and sea-disposal sites for untreated wastes.

Incineration provides a viable, although not inexpensive, alternative that produces scrubbable gaseous and particulate contaminants from a myriad of waste products. Incinerators are used to burn municipal solid wastes, industrial chemical wastes, and sewage sludge. In general, the off-gases can be classified according to their corrosiveness in descending order as follows: industrial chemical, municipal solid, and sewage sludge.

Industrial Chemical. These gases are characterized by extremely high temperatures (1000 °C, or 1830 °F, is not uncommon) and the presence of halogenated compounds. In many cases, chlorinated hydrocarbons and plastics are burned, producing HCl, chlorine, hydrogen fluoride (HF), and possibly hydrogen bromide. Some sulfur and phosphorus compounds may also be produced.

The typical treatment systems uses a gas quench to saturate and cool the gases, a wet venturi scrubber (if particulates pose a problem), a packed tower absorber, exhaust fan, ducting, liquid piping, and liquid recirculation pumps. Figure 2 shows a standard system arrangement.

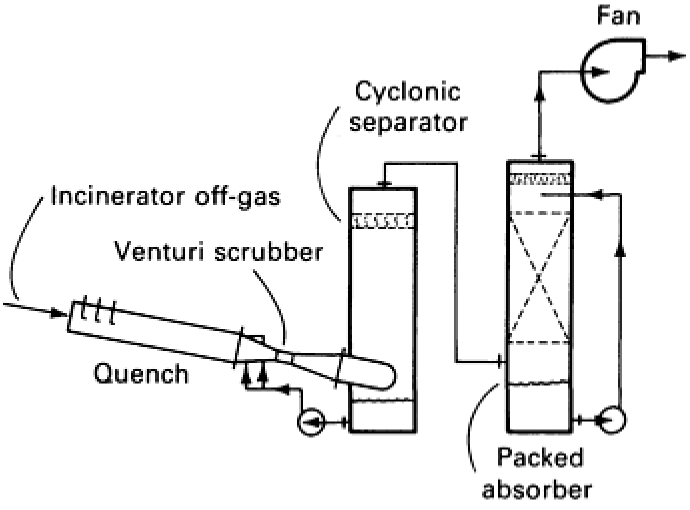

Fig. 2 Schematic of a general scrubber system arrangement

Because of high temperatures, the presence of chlorides, and the fact that the gas becomes saturated with water vapor within the quench, very few materials can be successfully used for the quench construction. The major problem is not uniform attack but local pitting and crevice corrosion of many metals. In particular, chloride stress-corrosion cracking severely affects austenitic stainless steels.

The materials that have found to perform very well are such high-nickel alloys as Hastelloy C-276, Inconel 625, and titanium for the highest-temperature cases and Hastelloy G and G-3 for slightly less severe cases. These materials have been used in other critical areas of the treatment system, such as fan wheels, dampers, liquid spray nozzles, and piping. Multiple-year service life histories have been reported with these alloys (Ref 4.)

Refractory linings for the quench have also been used with some success. This can sometimes prove to be a more economical alternative to the use of high-nickel alloys. Problems do occur, however, because of attack on the binding substances employed and on the carbon steel base material, if exposed.

Following the quench, where temperatures are typically less than 95 °C (205 °F), the major equipment (venturis, tower shells, sump tanks, fan housings, and pump bodies) can be constructed of FRP. A premium polyester or vinyl-ester resin can withstand even the most severe corrosive atmospheres at these milder temperatures. Even the presence of glass-attacking fluorides would not preclude the use of FRP, given the availability of synthetic veils used to replace glass veils within the resin layers closest to the internally exposed surfaces.

The recirculating fluids, often alkaline because of the need to scrub acidic gases, can often be handled satisfactorily by FRP or such thermoplastics as CPVC and PP. In this case, the alkalinity is not the problem. Free chlorides and fluorides may be present even in the most carefully operated and maintained systems.

Fiberglass-reinforced plastic ductwork is used to transport the gases in the milder-temperature areas of the system. Because PP exhibits good resistance to most of the corrosives usually encountered, it is used for tower packing, mist eliminators, and spray nozzles. It is a particularly good choice for environments having the potential for severe fluoride attack. The use of rubberlined components can be successful, but the emergence of sound FRP construction has limited its popularity.

Caution must be exercised when using plastics in the system following the quench. If the quench loses its liquid and there are no safeguards, a major part of the downstream equipment may be destroyed. Typically, temperatures are monitored so that an emergency cooling liquids source, possibly city water, is injected into the quench to prevent disastrous temperature excursions if the normal liquid source is lost.

A more conservative approach that is implemented in many system designs would also use high-nickel alloy construction for the equipment directly downstream of the quench. In any case, this question must be addressed during the design phase of any incineration project.

Municipal Solid Waste. The by-products of solid municipal wastes can be similar to those found in chemical incineration. The levels of the worst contaminants--chlorides, for example--are usually lower. The nature of the requirements for burning these wastes, which contain large portions of cellulose, result in lower off-gas temperatures than those for chemical incineration.

Nevertheless, corrosion problems are severe, and materials selection is not very different from that of industrial chemicals incineration. Reference 5 provides a ranking of metals with respect to corrosion resistance on the basis of corrosion tests in this service. In addition, Ref 6 shows the results of corrosion tests for a very wide range of alloys in six distinct system zones.

Sewage Sludge. The burning of sewage sludge presents the least corrosive discharge of the three types under discussion. This can be attributed to limited halogen compounds in the gas and somewhat lower temperatures (typically 315 to 650 °C, or 600 to 1200 °F.

Type 304 and 316 stainless steels are suitable for construction in most areas of the system, including the quenching area, whether as a separate quench or part of the wet scrubber. Again, FRP, thermoplastics, and lined carbon steel can be used in the cooler regions.

The predominant contaminants in the environment are odorous sulfur compounds, both organic (mercaptans) and inorganic (hydrogen sulfide, H_2S), and particulate. Chlorides can exist, but they normally originate from the water used for makeup. Their presence sometimes requires the use of high-nickel alloys for such components as fan wheels and pump impellers.

Erosion can be a significant problem in any of these systems. It can wear down critical moving mechanical components and equipment walls at points of liquid and/or gas impingement and, perhaps more importantly, it can contribute to corrosion attack.

The overall effect is not as severe as that found with FGD treatment equipment, but there are a number of areas of concern. The venturi throat and spray nozzles can suffer some abrasion. Fan wheels and pump impellers, however, usually the most critical areas in these systems with respect to potential problems.

The use of high-nickel alloys at these points has been noted above. Rubber lining can also be used, although generally not on fan wheels. Fiberglass-reinforced plastic can also be fabricated with silicon carbide impregnation for increased abrasion resistance for the internal surfaces.

Bulk Solids

Bulk solids processes include many different industries. The one thing they have in common is the need to handle dust collection for air pollution control.

Examples of this type of process include grain handling, foundries, coal handling, pneumatic conveying systems, and spray-drying systems. In every case, fine particles of dust can become entrained in the exhaust air and must be removed prior to discharge of the air. The three most common types of dust collection equipment are fabric filters, electrostatic precipitators, and wet scrubbers.

The selection of materials of construction does vary with the industry, but the dust handled is generally not severely corrosive. Carbon steel is the most common material of construction.

In selecting a dust collector, the most common construction for the vessel itself is steel, but the fabric used in the collection varies greatly. The manufacturers of fabric filters will have the greatest experience with selection for a specific application. Their expertise should be used in evaluating the relative initial maintenance cost for alternate fabrics. Typically, most bulk-handling applications can be managed with the use of PP for the filter bags. Currently, the cost of PP filter bags is close to that cotton filter bags. The low initial cost of PP makes it a versatile material of construction for this application. It does not rot when it becomes wet and offers relatively good corrosion resistance. The primary limitation is temperature.

Fans and stacks located downstream from a fabric filter are normally constructed of carbon steel. Because most of the dust has already been collected before it reaches this point, abrasion is not a major concern in the design of the downstream components.

Where extremely high performance is required, an electrostatic precipitator can be applied to a bulk solids application. This normally occurs in relatively dry services with inert particles. As such, the materials of construction are typically carbon steel.

Wet scrubbers are often used where the solids being handled are more reactive. For example, if there is a concern over the potential for an explosive mixture of the dust with air, the wet scrubber eliminates this problem. Wet scrubbers are also versatile and can simultaneously remove dust and gas.

Where scrubbers are applied, their low initial cost is partially by the need to recirculate a water-base solution. Care must be taken to ensure that this solution does not become corrosive or, if it does, to select the proper materials of construction for this specific case.

Commonly, general nuisance dust that is collected by a scrubber does not cause a direct corrosion problem. Instead, the problems arise because of the need to minimize the wastewater from the scrubber. For example, if the inlet is at ambient conditions, the scrubber will evaporate 122 L/h (31.8 gal/h) for every 10,000 m^3/h (5889 ft^3/min). If the solids quantity requires only 10% of the evaporation rate as a liquid bleed rate, then the dissolved solids in the water will be concentrated by a factor of ten. Thus, 200 ppm of chloride would suddenly become 2000 ppm of chloride. This would be sufficient to cause corrosion problems.

In most cases, fiberglass has been considered as a material of construction where abrasion is not particularly severe. In other cases, carbon steel is used, particularly for coal handling or other applications in which abrasion is definitely present.

Spray-drying applications typically require stainless steel. Either type 304 or 316 is used, depending on the particular compound being collected. The use of stainless steel arises from the need for product purity. Because the slurry is usually returned to the spray dryer, care must be taken to avoid any potential corrosion.

Chemical and Related Processing Plants

Chemical process and related industries experience a wide variety of potential corrosion problems. Many of the compounds used have severe effects on many materials of construction. For air pollution control, the quantities of these compounds can be greatly reduced, but the same corrosion problems may still be encountered. Obviously, it is important to rely on the experience of the plant with its process equipment in selecting air pollution control equipment for exhaust ventilation and process vents.

There are some specific differences, and the most important is the difference in operating pressure. Typically, the ventilation systems of chemical reactors will be at atmospheric pressure. By comparison, the reactor itself may be at several atmospheres of pressure. This is important because more economical materials of construction can often be selected for the ventilation system, but they would not have the mechanical strength necessary to handle the pressure in the reactor.

Because fiberglass can be used for atmospheric conditions, many of the clean-up systems used in chemical and process plants are fabricated from fiberglass. The primary reason for using FRP is its low initial cost and good corrosion resistance in a wide variety of services. The corrosion resistance of FRP is a function of both the resin content and the specific resin used in the laminate.

Chloro-Alkali Plants. The production of chlorine results in severe corrosion problems. Quantities of chlorine in the effluent gas are normally scrubbed using dilute caustic solutions. The most common material of construction is fiberglass. Although fiberglass can be used in chlorine service, specific types of resin must be employed for this very difficult application. Vinyl-ester resins are most commonly used. Numerous resins of the vinyl-ester type are available that can handle chlorine and chlorides. In addition to using a high-performance resin, the inner glass reinforcement is usually replaced with a synthetic veil to provide additional protection and to avoid any attack by hypochlorite or caustic on the inner liner.

Fiberglass-reinforced plastic is typically used for the scrubbers handling chlorine removal, ductwork, fans, and stacks. Even recycled pumps are manufactured of this material.

Where heat exchanges are used in the recycled solution, fiberglass is obviously not a practical material because of its low heat transfer coefficient. For dilute hypochlorite solutions, such alloys as Hastelloy C-276 or Inconel 625 have been used. Graphite can be used if the proper binder is selected. With the high heat transfer coefficients of plate heat exchangers, constructions of Hastelloy C-276 can be economical.

Polyvinyl chloride or high temperature PVC (CPVC) is another material of construction that performs well in this service. These materials are sometimes selected for small units or for ductwork construction.

Nitric Acid Plants. In nitric acid (HNO_3) manufacture, stainless steel is the most common material of construction. Concentrated HNO_3 will affect many of the nonmetallic materials of construction; therefore, FRP is not as common or as easily accepted.

For many ventilation systems, either type 304 stainless steel or CPVC could be used. Fiberglass-reinforced plastic could also be used when the acid is being neutralized. Relative costs are shown in Figure 3. Because the cost of stainless steel is still relatively high compared to that of FRP, this alternative should be considered where very dilute acid concentrations are involved. Where concentration and return to the process are involved, stainless steel remains the best solution.

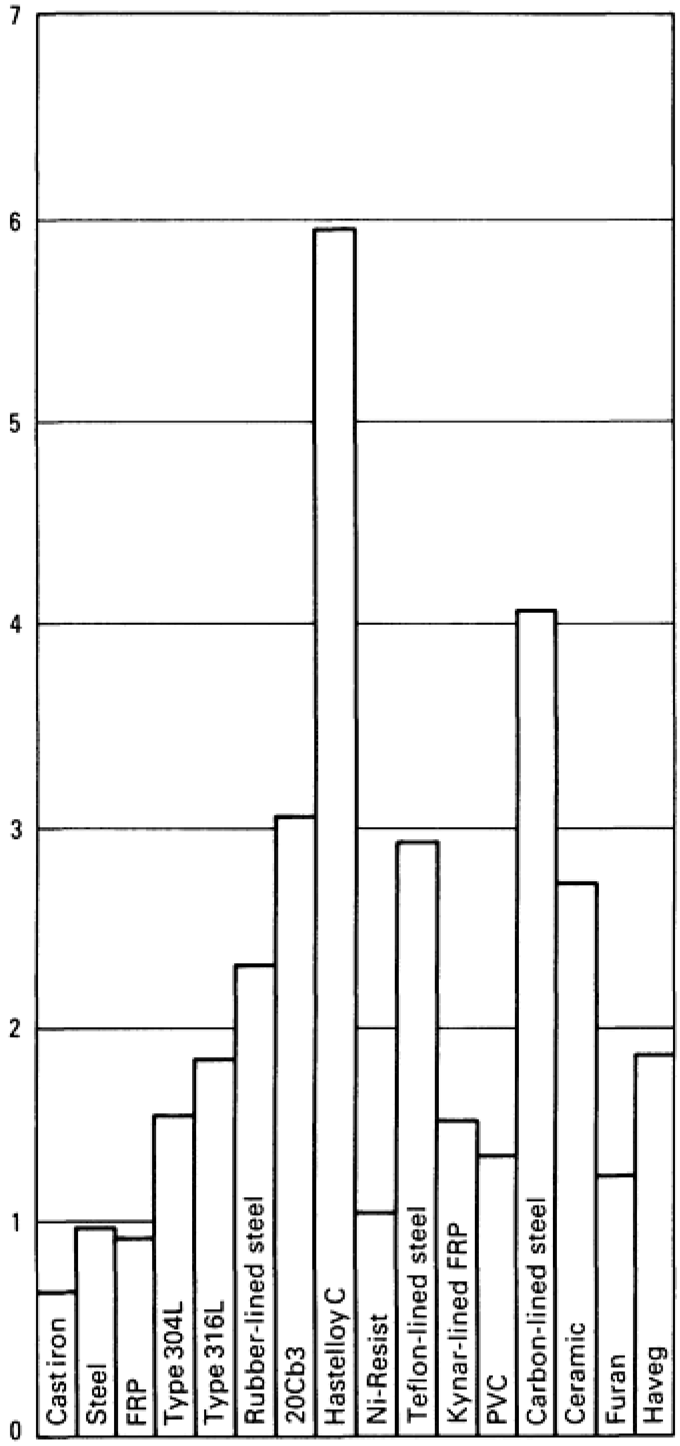

Fig. 3 Relative costs of scrubber materials

In many cases, HNO_3 manufacture also produces oxides of nitrogen. Nitric oxide (NO) and nitrogen dioxide (NO_2) would be handled by the same materials of construction. Most commonly, these are removed from the air by using scrubbing systems.The recycled solution becomes a dilute HNO_3 solution. A special wet-phase catalyst has been developed for use on this service. This material has properties very similar to those of stainless steel.

In other HNO_3 facilities, thermal reduction has been used to eliminate the residual oxides of nitrogen from the air. Where thermal reduction is used, there is no wet surface. However, the possibility of condensation remains should the system shut down. Therefore, the holders in such units are typically stainless steel. The catalyst itself is normally a ceramic material with a vanadium oxide or similar catalyst applied to the surface. These materials are selected by the manufacturers and would be compatible with stainless steel components selected for ductwork, fans, and other auxiliaries.

Sulfuric Acid Service. Sulfuric acid mist is collected by fiber bed mist eliminators. Such units employ a glass mat held inside of a vessel operating at low velocities to remove submicron mists.

Fiber bed unit shells for H_2SO_4 are either type 316 stainless steel or alloy 20Cb3. The relative economics suggest the use type 316 stainless steel, although it may suffer a small amount of attack.

Alloy 20Cb3 can be used for most ranges of acid that would be encountered in air pollution control systems. If the solution is weak enough, type 316 stainless steel can be used. Also, if the temperatures are low enough, FRP should be considered because of its low initial cost. It is best to obtain coupons of the materials and to conduct some initial testing at dilute conditions before making a final decision. The industry practice is to use more and more FRP on these inorganic acid applications because of low initial cost.

Sulfur Dioxide Service. Sulfur dioxide has similar requirements even though the initial solution formed is usually a neutralized salt; that is, SO_2 is normally absorbed using an alkali solution, such as lime or caustic. This solution is a sodium or calcium sulfite/sulfate mixture. It can be handled at low temperatures in fiberglass and at higher temperatures in type 316L stainless steel.

Because most of the gas is removed in the air pollution control equipment, the downstream equipment can often handled using liners rather than expensive alloys. This is particularly true for the fan because epoxy coatings can be applied to the fan housing. The wheel itself is recommended in solid alloy construction because of high speeds involved. The combination of an epoxy liner and a stainless steel wheel can cost as much as 25% less than a solid stainless steel fan.

Discharge stacks are often treated on the same basis. Where the stacks are large enough, a coating can be applied to a steel stack. Of course, the first selection might be an FRP stack if the temperature is low enough because of its elimination

of maintenance. More information on materials of construction for the chemical-processing industry is available in the article "Corrosion in the Chemical-Processing Industry" in this Volume.

The Fertilizer Industry. Several severe problems can occur in the manufacture of fertilizers. Trace quantities of fluorides in phosphates result in the formation of HF and tetrafluoride in the gas. Although these can be scrubbed out, the resulting solution is extremely corrosive to most metals and fiberglass.

The most common solution is the use of FRP, but with the substitution of synthetic veils for the inner glass lining. The FRP resin itself is not affected by the HF, but the internal glass could be. A small pinhole leading to the glass would result in a catastrophic attack. This is avoided by substituting a synthetic veil for the glass. Fiberglass is used throughout the industry as a standard. Polypropylene, PVC, and similar thermoplastics are also used. Nitrates and urea products are typically handled by using type 304 stainless steel. As noted above, concentrated HNO_3 could attack FRP-type materials.

Lime Kiln and Similar Kiln Operations. Lime kilns are found in several applications, including the pulp and the paper industry. Lime and other kiln applications result in a hot gas that contains dust.

Most kilns use a pollution control system. When possible, a dry collection system is used, because it allows the material to be collected in a form that can be returned directly to the kiln. Some products are simply too reactive for this technique, or the temperature of the kiln is too high. Wet scrubbers are then used.

Most of the scrubbers on kilns are manufactured of carbon steel. The problem of corrosion resistance is usually minimal because the solutions tend to be alkaline or at least neutral. The primary problem is usually abrasion resistance. The basic collectors are manufactured of carbon steel, and high-wear areas are often made of stainless steel. Some units use heat-treated stainless steel, which is hardened for the wear-resistant areas. Another technique is to install liner to protect areas of greater wear. Fiberglass-reinforced plastic is typically not used in this application.

Pulp and Paper Industry. Most of the pollution control problems in the pulp and paper industry consist of either the organic sulfur compounds produced from digesting the pulp or the chlorine-related oxidizing agents produced from bleaching the pulp. The reduced sulfur compounds are generally handled in FRP construction. Temperature limitations are not normally a factor, because most of these applications are at temperatures of 80 °C (175 °F) or less Chlorine or chlorine dioxide applications can be handled by materials of construction similar to those discussed in the section "Chloro-Alkali Plants." More information on materials of construction for the pulp and paper industry is available in the article "Corrosion in the Pulp and Paper Industry" in this Volume.

Corrosion Rate Conversion Guide

Introduction

CORROSION RATE is the corrosion effect on a metal (change or deterioration) per unit of time. The type of corrosion rate used depends on the technical system and on the type of corrosion effect. Thus, corrosion rate may be expressed as an increase in corrosion depth per unit of time (penetration rate, for example, mils/yr) or the mass of metal turned into corrosion products per unit area of surface per unit of time (weight loss, for example, $g/m^2/d$). The corrosion effect may vary with time and may not be the same at all points of the corroding surface. Therefore, reports of corrosion rates should be accompanied by information on the type, time dependency, and location of the corrosion effect.

Conversion of Corrosion Rates

Table 1 provides factors for converting among units commonly used for expressing corrosion rates. Table 2 is a nomograph for conversion of corrosion rates.

Table 1 Relationships among some of the units commonly used for corrosion rates

d is metal density in grams per cubic centimeter (g/cm^3)

Unit	**Factor for conversion to**					
	mdd	**$g/m^2/d$**	**µm/yr**	**mm/yr**	**mils/yr**	**in./yr**
Milligrams per square decimeter per day (mdd)	1	0.1	36.5/*d*	0.0365/*d*	1.144/*d*	0.00144/*d*
Grams per square meter per day ($g/m^2/d$	10	1	365/*d*	0.365/*d*	14.4/*d*	0.0144/*d*
Microns per year (µm/yr)	0.0274*d*	0.00274*d*	1	0.001	0.0394	0.0000394
Millimeters per year (mm/yr)	27.4*d*	2.74*d*	1000	1	39.4	0.0394
Mils per year (mils/yr)	0.696*d*	0.0696*d*	25.4	0.0254	1	0.001
Inches per year (in./yr)	696*d*	69.6*d*	25,400	25.4	1000	1

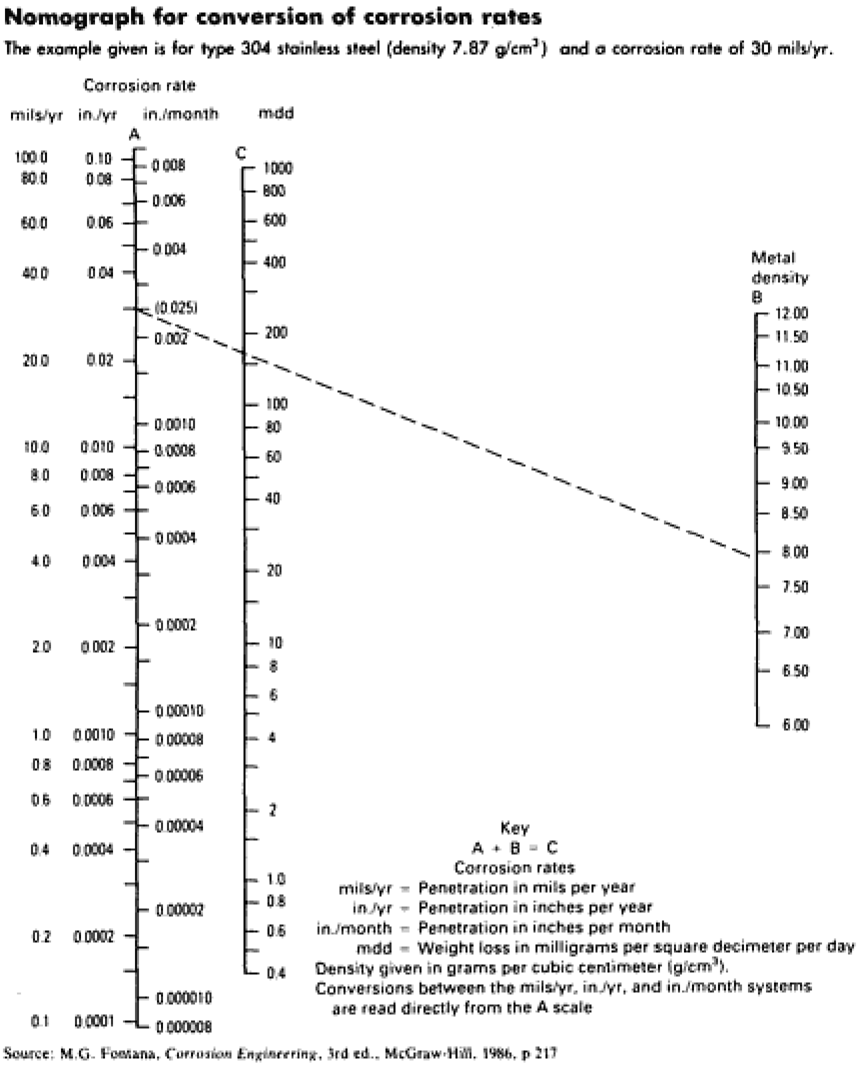
Table 2 Nomograph for conversion of corrosion rates.

The example given is for type 304 stainless steel (density 7.87 g/cm^3) and a corrosion rate of 30 mils/yr.



Glossary of Terms

- **A**
- **absorption**
  - A process in which fluid molecules are taken up by a liquid or solid and distributed throughout the body of that liquid or solid. Compare with adsorption .
- **accelerated corrosion test**
  - Method designed to approximate, in a short time, the deteriorating effect under normal long-term service conditions.
- **acid**
  - A chemical substance that yields hydrogen ions (H^+) when dissolved in water. Compare with base .
- **acid embrittlement**
  - A form of hydrogen embrittlement that may be induced in some metals by acid.
- **acid rain**
  - Atmospheric precipitation with a pH below 5.6 to 5.7. Burning of fossil fuels for heat and power is the major factor in the generation of oxides of nitrogen and sulfur, which are converted into nitric and sulfuric acids washed down in the rain. See also atmospheric corrosion .
- **acicular ferrite**

- A highly substructured non-equiaxed ferrite formed upon continuous cooling by a mixed diffusion and shear mode of transformation that begins at a temperature slightly higher than the transformation temperature range for upper bainite. It is distinguished from bainite in that it has a limited amount of carbon available; thus, there is only a small amount of carbide present.
- **acrylic**
  - Resin polymerized from acrylic acid, methacrylic acid, esters of these acids, or acrylonitrile.
- **activation**
  - The changing of a passive surface of a metal to a chemically active state. Contrast with passivation .
- **active**
  - The negative direction of electrode potential . Also used to described corrosion and its associated potential range when an electrode potential is more negative than an adjacent depressed corrosion rate (passive) range.
- **active metal**
  - A metal ready to corrode, or being corroded.
- **active potential**
  - The potential of a corroding material.
- **activity**
  - A measure of the chemical potential of a substance, where chemical potential is not equal to concentration, that allows mathematical relations equivalent to those for ideal systems to be used to correlate changes in an experimentally measured quantity with changes in chemical potential.
- **activity (ion)**
  - The ion concentration corrected for deviations from ideal behavior. Concentration multiplied by activity coefficient.
- **activity coefficient**
  - A characteristic of a quantity expressing the deviation of a solution from ideal thermodynamic behavior; often used in connection with electrolytes.
- **addition agent**
  - A substance added to a solution for the purpose of altering or controlling a process. Examples include wetting agents in acid pickles, brighteners or antipitting agents in plating solutions, and inhibitors.
- **adsorption**
  - The surface retention of solid, liquid, or gas molecules, atoms, or ions by a solid or liquid. Compare with absorption .
- **aeration**
  - (1) Exposing to the action of air. (2) Causing air to bubble through. (3) Introducing air into a solution by spraying, stirring, or a similar method. (4) Supplying or infusing with air, as in sand or soil.
- **aeration cell (oxygen cell)**
  - See differential aeration cell .
- **age hardening**
  - Hardening by aging , usually after rapid cooling or cold working.
- **aging**
  - A change in the properties of certain metals and alloys that occurs at ambient or moderately elevated temperatures after hot working or a heat treatment (quench aging in ferrous alloys, natural or artificial aging in ferrous and nonferrous alloys) or after a cold-working operation (strain aging). The change in properties is often, but not always, due to a phase change (precipitation), but never involves a change in chemical composition of the metal or alloy. See also age hardening , artificial aging , natural aging , overaging , precipitation hardening , precipitation heat treatment , quench aging , and strain aging .
- **alclad**
  - Composite wrought product comprised of an aluminum alloy core having on one or both surfaces a metallurgically bonded aluminum or aluminum alloy coating that is anodic to the core and thus electrochemically protects the core against corrosion.
- **alkali metal**
  - A metal in group IA of the periodic system--namely, lithium, sodium, potassium, rubidium, cesium, and francium. They form strongly alkaline hydroxides, hence the name.
- **alkaline**

- (1) Having properties of an alkali. (2) Having a pH greater than 7.
- **alkaline cleaner**
  - A material blended from alkali hydroxides and such alkaline salts as borates, carbonates, phosphates, or silicates. The cleaning action may be enhanced by the addition of surface-active agents and special solvents.
- **alkyd**
  - Resin used in coatings. Reaction products of polyhydric alcohols and polybasic acids.
- **alkylation**
  - (1) A chemical process in which an alkyl radical is introduced into an organic compound by substitution or addition. (2) A refinery process for chemically combining isoparaffin with olefin hydrocarbons.
- **alligatoring**
  - (1) Pronounced wide cracking over the entire surface of a coating having the appearance of alligator hide. (2) The longitudinal splitting of flat slabs in plane parallel to the rolled surface. Also called fish-mouthing.
- **alloy plating**
  - The codeposition of two or more metallic elements.
- **alpha ferrite**
  - See ferrite .
- **alpha iron**
  - The body-centered cubic form of pure iron, stable below 910 °C (1670 °F).
- **alternate-immersion test**
  - A corrosion test in which the specimens are intermittently exposed to a liquid medium at definite time intervals.
- **aluminizing**
  - Forming of an aluminum or aluminum alloy coating on a metal by hot dipping, hot spraying, or diffusion.
- **amalgam**
  - An alloy of mercury with one or more other metals.
- **ammeter**
  - An instrument for measuring the magnitude of electric current flow.
- **amorphous solid**
  - A rigid material whose structure lacks crystalline periodicity; that is, the pattern of its constituent atoms or molecules does not repeat periodically in three dimensions. See also metallic glass.
- **amphoteric**
  - A term applied to oxides and hydroxides which can act basic toward strong acids and acidic toward strong alkalis. Substances which can dissociate electrolytically to produce hydrogen or hydroxyl ions according to conditions.
- **anchorite**
  - A zinc-iron phosphate coating for ion and steel.
- **anaerobic**
  - Free of air or uncombined oxygen.
- **anion**
  - A negatively charged ion that migrates through the electrolyte toward the anode under the influence of a potential gradient. See also cation and ion .
- **annealing**
  - A generic term denoting a treatment, consisting of heating to and holding at a suitable temperature, followed by cooling at a suitable rate, used primarily to soften metallic materials, but also to simultaneously produce desired changes in other properties or in microstructure. The purpose of such changes may be, but is not confined to, improvement of machinability, facilitation of cold work, improvement of mechanical or electrical properties, and/or increase in stability of dimensions. When the term is used by itself, full annealing is implied. When applied only for the relief of stress, the process is properly called stress relieving or stress-relief annealing.
- **anode**
  - The electrode of an electrolyte cell at which oxidation occurs. Electrons flow away from the anode in the external circuit. It is usually at the electrode that corrosion occurs and metal ions enter solution. Contrast with cathode .

- **anode corrosion**
  - The dissolution of a metal acting as an anode .
- **anode corrosion efficiency**
  - The ratio of the actual corrosion (weight loss) of an anode to the theoretical corrosion (weight loss) calculated by Faraday's law from the quantity of electricity that has passed.
- **anode effect**
  - The effect produced by polarization of the anode in electrolysis. It is characterized by a sudden increase in voltage and corresponding decrease in amperage due to the anode becoming virtually separated from the electrolyte by a gas film.
- **anode efficiency**
  - Current efficiency at the anode .
- **anode film**
  - (1) The portion of solution in immediate contact with the anode , especially if the concentration gradient is steep. (2) The outer layer of the anode itself.
- **anode polarization**
  - See polarization .
- **anodic cleaning**
  - Electrolytic cleaning in which the work is the anode. Also called reverse-current cleaning.
- **anodic coating**
  - A film on a metal surface resulting from an electrolytic treatment at the anode .
- **anodic inhibitor**
  - A chemical substance or mixture that prevents or reduces the rate of the anodic or oxidation reaction. See also inhibitor .
- **anodic polarization**
  - The change of the electrode potential in the noble (positive) direction due to current flow. See also polarization .
- **anodic protection**
  - (1) A technique to reduce the corrosion rate of a metal by polarizing it into its passive region, where dissolution rates are low. (2) Imposing an external electrical potential to protect a metal from corrosive attack. (Applicable only to metals that show active-passive behavior.) Contrast with cathodic protection .
- **anodic reaction**
  - Electrode reaction equivalent to a transfer of positive charge from the electronic to the ionic conductor. An anodic reaction is an oxidation process. An example common in corrosion is: $Me \longrightarrow Me^{n+} + ne^{-}$.
- **anodizing**
  - Forming a conversion coating on a metal surface by anodic oxidation; most frequently applied to aluminum.
- **anolyte**
  - The electrolyte adjacent to the anode in an electrolytic cell .
- **anti-fouling**
  - Intended to prevent fouling of underwater structures, such as the bottoms of ships.
- **antipitting agent**
  - An addition agent for electroplating solutions to prevent the formation of pits or large pores in the electrodeposit.
- **aqueous**
  - Pertaining to water; an aqueous solution is made by using water as a solvent.
- **artificial aging**
  - Aging above room temperature. See also aging . Compare with natural aging .
- **atmospheric corrosion**
  - The gradual degradation or alteration of a material by contact with substances present in the atmosphere, such as oxygen, carbon dioxide, water vapor, and sulfur and chlorine compounds.
- **austenite**
  - A solid solution of one or more elements in face-centered cubic iron. Unless otherwise designated (such as nickel austenite), the solute is generally assumed to be carbon.
- **austenitizing**

- Forming austenite by heating a ferrous alloy into the transformation range (partial austenitizing) or above the transformation range (complete austenitizing). When used without qualification, the term implies complete austenitizing.
- **auxiliary anode**
  - In electroplating, a supplementary anode positioned so as to raise the current density on a certain area of the cathode and thus obtain better distribution of plating.
- **auxiliary electrode**
  - An electrode commonly used in polarization studies to pass current to or from a test electrode. It is usually made from a noncorroding material.
- **B**
- **backfill**
  - Material placed in a drilled hole to fill space around anodes, vent pipe, and buried components of a cathodic protection system.
- **bainite**
  - A metastable aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures below the pearlite range but above M_s, the martensite start temperature. Bainite formed in the upper part of the bainite transformation range has a feathery appearance; bainite formed in the lower part of the range has an acicular appearance resembling that of tempered martensite.
- **banded structure**
  - A segregated structure consisting of alternating nearly parallel bands of different composition, typically aligned in the direction of primary hot working.
- **base**
  - A chemical substance that yields hydroxyl ions (OH^-) when dissolved in water. Compare with acid .
- **base metal**
  - (1) The metal present in the largest proportion in an alloy; brass, for example, is a copper-base alloy. (2) An active metal that readily oxidizes, or that dissolves to form ions. (3) The metal to be brazed, cut, soldered, or welded. (4) After welding, that part of the metal which was not melted.
- **beach marks**
  - Macroscopic progression marks on a fatigue fracture or stress-corrosion cracking surface that indicate successive positions of the advancing crack front. The classic appearance is of irregular elliptical or semielliptical rings, radiating outward from one or more origins. Beach marks (also known as clamshell marks or arrest marks) are typically found on service fractures where the part is loaded randomly, intermittently, or with periodic variations in mean stress or alternating stress. See also striation .
- **biaxial stress**
  - See principal stress (normal) .
- **biological corrosion**
  - Deterioration of metals as a result of the metabolic activity of microorganisms.
- **bipolar electrode**
  - An electrode in an electrolytic cell that is not mechanically connected to the power supply, but is so placed in the electrolyte, between the anode and cathode , that the part nearer the anode becomes cathodic and the part nearer the cathode becomes anodic. Also called intermediate electrode.
- **bituminous coating**
  - Coal tar or asphalt-base coating.
- **black liquor**
  - The liquid material remaining from pulpwood cooking in the soda or sulfate papermaking process.
- **black oxide**
  - A black finish on a metal produced by immersing it in hot oxidizing salts or salt solutions.
- **blister**
  - A raised area, often dome shaped, resulting from (1) loss of adhesion between a coating or deposit and the base metal or (2) delamination under the pressure of expanding gas trapped in a metal in a near-subsurface zone. Very small blisters may be called pinhead blisters or pepper blisters.
- **blow down**

- (1) Injection of air or water under high pressure through a tube to the anode area for the purpose of purging the annular space and possibly correcting high resistance caused by gas blocking. (2) In connection with boilers or cooling towers, the process of discharging a significant portion of the aqueous solution in order to remove accumulated salts, deposits, and other impurities.
- **blue brittleness**
  - Brittleness exhibited by some steels after being heated to a temperature within the range of about 200 to 370 °C (400 to 700 °F), particularly if the steel is worked at the elevated temperature.
- **blushing**
  - Whitening and loss of gloss of a usually organic coating caused by moisture. Also called blooming.
- **brackish water**
  - (1) Water having salinity values ranging from approximately 0.5 to 17 parts per thousand. (2) Water having less salt than seawater, but undrinkable.
- **breakdown potential**
  - The last noble potential where pitting or crevice corrosion , or both, will initiate and propagate.
- **brightener**
  - An agent or combination of agents added to an electroplating bath to produce a smooth, lustrous deposit.
- **brine**
  - Seawater containing a higher concentration of dissolved salt than that of the ordinary ocean.
- **brittle fracture**
  - Separation of a solid accompanied by little or no macroscopic plastic deformation. Typically, brittle fracture occurs by rapid crack propagation with less expenditure of energy than for ductile fracture .
- **burning**
  - (1) Permanently damaging a metal or alloy by heating to cause either incipient melting or intergranular oxidation. See also overheating . (2) In grinding, getting the work hot enough to cause discoloration or to change the microstructure by tempering or hardening.
- **C**
- **calcareous coating or deposit**
  - A layer consisting of a mixture of calcium carbonate and magnesium hydroxide deposited on surfaces being cathodically protected because of the increased pH adjacent to the protected surface.
- **calomel electrode**
  - An electrode widely used as a reference electrode of known potential in electrometric measurement of acidity and alkalinity, corrosion studies, voltammetry, and measurement of the potentials of other electrodes. See also electrode potential , reference electrode , and saturated calomel electrode .
- **calorizing**
  - Imparting resistance to oxidation to an iron or steel surface by heating in aluminum powder at 800 to 1000 °C (1470 to 1830 °F).
- **carbonitriding**
  - A case hardening process in which a suitable ferrous material is heated above the lower transformation temperature in a gaseous atmosphere of such composition as to cause simultaneous absorption of carbon and nitrogen by the surface and, by diffusion, create a concentration gradient. The process is completed by cooling at a rate that produces the desired properties in the workpiece.
- **carburizing**
  - Absorption and diffusion of carbon into solid ferrous alloys by heating, to a temperature usually above Ac_3, in contact with a suitable carbonaceous material. A form of case hardening that produces a carbon gradient extending inward from the surface, enabling the surface layer to be hardened either by quenching directly from the carburizing temperature or by cooling to room temperature, then reaustenitizing and quenching.
- **case hardening**
  - A generic term covering several processes applicable to steel that change the chemical composition of the surface layer by absorption of carbon, nitrogen, or a mixture of the two and, by diffusion, create a concentration gradient. The outer portion, or case, is made substantially harder than the inner portion, or core. The processes commonly used are carburizing and quench

hardening; cyaniding; nitriding; and carbonitriding. The use of the applicable specific process name is preferred.

- **CASS test**
  - See copper-accelerated salt-spray test .
- **cathode**
  - The electrode of an electrolytic cell at which reduction is the principal reaction. (Electrons flow toward the cathode in the external circuit.) Typical cathodic processes are cations taking up electrons and being discharged, oxygen being reduced, and the reduction of an element or group of elements from a higher to a lower valence state. Contrast with anode .
- **cathode efficiency**
  - Current efficiency at the cathode .
- **cathode film**
  - The portion of solution in immediate contact with the cathode during electrolysis .
- **cathodic cleaning**
  - Electrolytic cleaning in which the work is the cathode .
- **cathodic corrosion**
  - Corrosion resulting from a cathodic condition of a structure usually caused by the reaction of an amphoteric metal with the alkaline products of electrolysis .
- **cathodic disbondment**
  - The destruction of adhesion between a coating and its substrate by products of a cathodic reaction .
- **cathodic inhibitor**
  - A chemical substance or mixture that prevents or reduces the rate of the cathodic or reduction reaction.
- **cathodic pickling**
  - Electrolytic pickling in which the work is the cathode .
- **cathodic polarization**
  - The change of the electrode potential in the active (negative) direction due to current flow. See also polarization .
- **cathodic protection**
  - (1) Reduction of corrosion rate by shifting the corrosion potential of the electrode toward a less oxidizing potential by applying an external electromotive force . (2) Partial or complete protection of a metal from corrosion by making it a cathode , using either a galvanic or an impressed current. Contrast with anodic protection .
- **cathodic reaction**
  - Electrode reaction equivalent to a transfer of negative charge from the electronic to the ionic conductor. A cathodic reaction is a reduction process. An example common in corrosion is: $\text{Ox} + ne^- \rightarrow \text{Red}$.
- **catholyte**
  - The electrolyte adjacent to the cathode of an electrolytic cell.
- **cation**
  - A positively charged ion that migrates through the electrolyte toward the cathode under the influence of a potential gradient. See also anion and ion .
- **caustic**
  - (1) Burning or corrosive. (2) A hydroxide of a light metal, such as sodium hydroxide or potassium hydroxide.
- **caustic dip**
  - A strongly alkaline solution into which metal is immersed for etching, for neutralizing acid, or for removing organic materials such as greases or paints.
- **caustic embrittlement**
  - An obsolete historical term denoting a form of stress-corrosion cracking most frequently encountered in carbon steels or iron-chromium-nickel alloys that are exposed to concentrated hydroxide solutions at temperatures of 200 to 250 °C (400 to 480 °F).
- **cavitation**
  - The formation and instantenous collapse of innumerable tiny voids or cavities within a liquid subjected to rapid and intense pressure changes. Cavitation produced by ultrasonic radiation is sometimes used to effect violent localized agitation. Cavitation caused by severe turbulent flow often leads to cavitation damage .

- **cavitation corrosion**
  - A process involving conjoint corrosion and cavitation .
- **cavitation damage**
  - The degradation of a solid body resulting from its exposure to cavitation . This may include loss of material, surface deformation, or changes in properties or appearance.
- **cavitation-erosion**
  - Progressive loss of original material from a solid surface due to continuing exposure to cavitation .
- **cell**
  - Electrochemical system consisting of an anode and a cathode immersed in an electrolyte . The anode and cathode may be separate metals or dissimilar areas on the same metal. The cell includes the external circuit, which permits the flow of electrons from the anode toward the cathode. See also electrochemical cell .
- **cementite**
  - A compound of iron and carbon, known chemically as iron carbide and having the approximate chemical formula Fe_3C. It is characterized by an orthorhombic crystal structure. When it occurs as a phase in steel, the chemical composition will be altered by the presence of manganese and other carbide-forming elements.
- **chalking**
  - The development of loose removable powder at the surface of an organic coating usually caused by weathering.
- **checking**
  - The development of slight breaks in a coating that do not penetrate to the underlying surface.
- **checks**
  - Numerous, very fine cracks in a coating or at the surface of a metal part. Checks may appear during processing or during service and are most often associated with thermal treatment or thermal cycling. Also called check marks, checking , or heat checks.
- **chelate**
  - (1) A molecular structure in which a heterocyclic ring can be formed by the unshared electrons of neighboring atoms. (2) A coordination compound in which a heterocyclic ring is formed by a metal bound to two atoms of the associated ligand. See also complexation .
- **chelating agent**
  - (1) An organic compound in which atoms form more than one coordinate bond with metals in solution. (2) A substance used in metal finishing to control or eliminate certain metallic ions present in undesirable quantities.
- **chelation**
  - A chemical process involving formation of a heterocyclic ring compound that contains at least one metal cation or hydrogen ion in the ring.
- **Chemical conversion coating**
  - A protective or decorative nonmetallic coating produced *in situ* by chemical reaction of a metal with a chosen environment. It is often used to prepare the surface prior to the application of an organic coating.
- **chemical potential**
  - In a thermodynamic system of several constituents, the rate of change of the Gibbs function of the system with respect to the change in the number of moles of a particular constituent.
- **chemical vapor deposition**
  - A coating process, similar to gas carburizing and carbonitriding, whereby a reactant atmosphere gas is fed into a processing chamber where it decomposes at the surface of the workpiece, liberating one material for either absorption by, or accumulation on, the workpiece. A second material is liberated in gas form and is removed from the processing chamber, along with excess atmosphere gas.
- **chemisorption**
  - The binding of an adsorbate to the surface of a solid by forces whose energy levels approximate those of a chemical bond. Contrast with physisorption .
- **chevron pattern**
  - A fractographic pattern of radial marks (shear ledges) that look like nested letters "V"; sometimes called a herringbone pattern. Chevron patterns are typically found on brittle fracture surfaces in

parts whose widths are considerably greater than their thicknesses. The points of the chevrons can be traced back to the fracture origin.

- **chromadizing**
  - Improving paint adhesion on aluminum or aluminum alloys, mainly aricraft skins, by treatment with a solution of chromic acid. Also called chromodizing or chromatizing. Not to be confused with chromating or chromizing.
- **chromate treatment**
  - A treatment of metal in a solution of a hexavalent chromium compound to produce a conversion coating consisting of trivalent and hexavalent chromium compounds.
- **chromating**
  - Performing a chromate treatment .
- **chrome pickle**
  - (1) Producing a chromate conversion coating on magnesium for temporary protection or for a paint base. (2) The solution that produces the conversion coating.
- **chromizing**
  - A surface treatment at elevated temperature, generally carried out in pack, vapor, or salt bath, in which an alloy is formed by the inward diffusion of chromium into the base metal.
- **clad metal**
  - A composite metal containing two or more layers that have been bonded together. The bonding may have been accomplished by co-rolling, co-extrusion, welding, diffusion bonding, casting, heavy chemical deposition, or heavy electroplating.
- **cleavage**
  - Splitting (fracture) of a crystal on a crystallographic plane of low index.
- **cleavage fracture**
  - A fracture, usually of a polycrystalline metal, in which most of the grains have failed by cleavage , resulting in bright reflecting facets. It is associated with low-energy brittle fracture .
- **cold cracking**
  - A type of weld cracking that usually occurs below 205 °C (400 °F). Cracking may occur during or after cooling to room temperature, sometimes with a considerable time delay. Three factors combine to produce cold cracks: stress (for example, from thermal expansion and contraction), hydrogen (from hydrogen-containing welding consumables), and a susceptible microstructure (plate martensite is most susceptible to cracking, ferritic and bainitic structures least susceptible). See also hot cracking , lamellar tearing , and stress-relief cracking .
- **cold working**
  - Deforming metal plastically under conditions of temperature and strain rate that induce strain hardening. Usually, but not necessarily, conducted at room temperature. Contrast with hot working .
- **combined carbon**
  - The part of the total carbon in steel or cast iron that is present as other than free carbon .
- **complexation**
  - The formation of complex chemical species by the coordination of groups of atoms termed ligands to a central ion, commonly a metal ion. Generally, the ligand coordinates by providing a pair of electrons that forms an ionic or covalent bond to the central ion. See also chelate , coordination compound , and ligand.
- **compressive**
  - Pertaining to forces on a body or part of a body that tend to crush, or compress, the body.
- **compressive strength**
  - The maximum compressive stress a material is capable of developing. With a brittle material that fails in compression by fracturing, the compressive strength has a definite value. In the case of ductile, malleable, or semiviscous materials (which do not fail in compression by a shattering fracture), the value obtained for compressive strength is an arbitrary value dependent on the degree of distortion that is regarded as effective failure of the material.
- **compressive stress**
  - A stress that causes an elastic body to deform (shorten) in the direction of the applied load. Contrast with tensile stress .
- **concentration cell**

- An electrolytic cell , the electromotive force of which is caused by a difference in concentration of some component in the electrolyte. This difference leads to the formation of discrete cathode and anode regions.

- **concentration polarization**
  - That portion of the polarization of a cell produced by concentration changes resulting from passage of current through the electrolyte.
- **conductivity**
  - The ratio of the electric current density to the electric field in a material. Also called electrical conductivity or specific conductance.
- **contact corrosion**
  - A term primarily used in Europe to describe galvanic corrosion between dissimilar metals.
- **contact plating**
  - A metal plating process wherein the plating current is provided by galvanic action between the work metal and a second metal, without the use of an external source of current.
- **contact potential**
  - The potential difference at the junction of two dissimilar substances.
- **continuity bond**
  - A metallic connection that provides electrical continuity between metals structures.
- **conversion coating**
  - A coating consisting of a compound of the surface metal, produced by chemical or electrochemical treatments of the metal. Examples include chromate coatings on zinc, cadmium, magnesium, and aluminum, and oxide and phosphate coatings on steel. See also chromate treatment and phosphating .
- **coordination compound**
  - A compound with a central atom or ion bound to a group of ions or molecules surrounding it. Also called coordination complex. See also chelate , complexation , and ligand.
- **copper-accelerated salt-spray (CASS) test**
  - An accelerated corrosion test for some electrodeposits and for anodic coatings on aluminum.
- **corrodkote test**
  - An accelerated corrosion test for electrodeposits.
- **corrosion**
  - The chemical or electrochemical reaction between a material, usually a metal, and its environment that produces a deterioration of the material and its properties.
- **corrosion effect**
  - A change in any part of the corrosion system caused by corrosion .
- **corrosion embrittlement**
  - The severe loss of ductility of a metal resulting from corrosive attack, usually intergranular and often not visually apparent.
- **corrosion-erosion.**
  - See erosion-corrosion .
- **corrosion fatigue**
  - The process in which a metal fractures prematurely under conditions of simultaneous corrosion and repeated cyclic loading at lower stress levels or fewer cycles than would be required in the absence of the corrosive environment.
- **corrosion fatigue strength**
  - The maximum repeated stress that can be endured by metal without failure under definite conditions of corrosion and fatigue and for a specific number of stress cycles and a specified period of time.
- **corrosion inhibitor**
  - See inhibitor .
- **corrosion potential**
  - (E_{corr}). The potential of a corroding surface in an electrolyte, relative to a reference electrode . Also called rest potential, open-circuit potential, or freely corroding potential.
- **corrosion product**
  - Substance formed as a result of corrosion .
- **corrosion protection**
  - Modification of a corrosion system so that corrosion damage is mitigated.

- **corrosion rate**
  - Corrosion effect on a metal per unit of time. The type of corrosion rate used depends on the technical system and on the type of corrosion effect. Thus, corrosion rate may be expressed as an increase in corrosion depth per unit of time (penetration rate, for example, mils/yr) or the mass of metal turned into corrosion products per unit area of surface per unit of time (weight loss, for example, $g/m^2/yr$). The corrosion effect may vary with time and may not be the same at all points of the corroding surface. Therefore, reports of corrosion rates should be accompanied by information on the type, time dependency, and location of the corrosion effect.
- **corrosion resistance**
  - Ability of a metal to withstand corrosion in a given corrosion system .
- **corrosion system**
  - System consisting of one or more metals and all parts of the environment that influence corrosion .
- **corrosivity**
  - Tendency of an environment to cause corrosion in a given corrosion system .
- **counterelectrode**
  - See auxiliary electrode .
- **couple**
  - See galvanic corrosion .
- **covering power**
  - The ability of a solution to give satisfactory plating at very low current densities, a condition that exists in recesses and pits. This term suggests an ability to cover, but not necessarily to build up, a uniform coating, whereas throwing power suggests the ability to obtain a coating of uniform thickness of an irregularly shaped object.
- **cracking (of coating)**
  - Breaks in a coating that extend through to the underlying surface.
- **crazing**
  - A network of checks or cracks appearing on the surface.
- **creep**
  - Time-dependent strain occurring under stress. The creep strain occurring at a diminishing rate is called primary creep; that occurring at a minimum and almost constant rate, secondary creep; and that occurring at an accelerating rate, tertiary creep.
- **creep-rupture embrittlement**
  - Embrittlement under creep conditions of, for example, aluminum alloys and steels that results in abnormally low rupture ductility. In aluminum alloys, iron in amounts above the solubility limit is known to cause such embrittlement; in steels, the phenomenon is related to the amount of impurities (for example, phosphorus, sulfur, copper, arsenic, antimony, and tin) present. In either case, failure occurs by intergranular cracking of the embrittled material.
- **creep-rupture strength**
  - The stress that will cause fracture in a creep test at a given time in a specified constant environment. Also called stress-rupture strength.
- **crevice corrosion**
  - Localized corrosion of a metal surface at, or immediately adjacent to, an area that is shielded from full exposure to the environment because of close proximity between the metal and the surface of another material.
- **critical anodic current density**
  - The maximum anodic current density observed in the active region for a metal or alloy electrode that exhibits active-passive behavior in an environment.
- **critical flaw size**
  - The size of a flaw (defect) in a structure that will cause failure at a particular stress level.
- **critical humidity**
  - The relative humidity above which the atmospheric corrosion rate of some metals increases sharply.
- **critical pitting potential (E_{cp}, E_p, E_{pp})**
  - The lowest value of oxidizing potential at which pits nucleate and grow. It is dependent on the test method used.
- **current**

- The net transfer of electric charge per unit time. Also called electric current. See also current density .
- **current density**
  - The current flowing to or from a unit area of an electrode surface.
- **current efficiency**
  - The ratio of the electrochemical equivalent current density for a specific reaction to the total applied current density.
- **D**
- **deactivation**
  - The process of prior removal of the active corrosive constituents, usually oxygen, from a corrosive liquid by controlled corrosion of expendable metal or by other chemical means, thereby making the liquid less corrosive.
- **dealloying**
  - The selective corrosion of one or more components of a solid solution alloy. Also called parting or selective leaching. See also decarburization , decobaltification , denickelification , dezincification , and graphitic corrosion .
- **decarburization**
  - Loss of carbon from the surface layer of a carbon-containing alloy due to reaction with one or more chemical substances in a medium that contacts the surface. See also dealloying .
- **decobaltification**
  - Corrosion in which cobalt is selectively leached from cobalt-base alloys, such as Stellite, or from cemented carbides. See also dealloying and selective leaching .
- **decomposition potential (or voltage)**
  - The potential of a metal surface necessary to decompose the electrolyte of a cell or a component thereof.
- **deep groundbed**
  - One or more anodes installed vertically at a nominal depth of 15 m (50 ft) or more below the earth's surface in a drilled hole for the purpose of supplying cathodic protection for an underground or submerged metallic structure. See also groundbed .
- **delta ferrite**
  - See ferrite .
- **dendrite**
  - A crystal that has a treelike branching pattern, being most evident in cast metals slowly cooled through the solidification range.
- **denickelification**
  - Corrosion in which nickel is selectively leached from nickel-containing alloys. Most commonly observed in copper-nickel alloys after extended service in fresh water. See also dealloying and selective leaching .
- **density (of gases)**
  - The mass of a unit volume of gas at a stated temperature and pressure.
- **density (of solids and liquids)**
  - The mass of unit volume of a material at a specified temperature.
- **deoxidizing**
  - (1) The removal of oxygen from molten metals by use of suitable deoxidizers. (2) Sometimes refers to the removal of undesirable elements other than oxygen by the introduction of elements or compounds that readily react with them. (3) In metal finishing, the removal of oxide films from metal surfaces by chemical or electrochemical reaction.
- **depolarization**
  - A decrease in the polarization of an electrode
- **depolarizer**
  - A substance that produces depolarization .
- **deposit corrosion**
  - Corrosion occurring under or around a discontinuous deposit on a metallic surface. also called poultice corrosion.
- **descaling**
  - Removing the thick layer of oxides formed on some metals at elevated temperatures.
- **dezincification**

- Corrosion in which zinc is selectively leached from zinc-containing alloys. Most commonly found in copper-zinc alloys containing less than 85% copper after extended service in water containing dissolved oxygen. See also dealloying and selective leaching .

- **dichromate treatment**
  - A chromate conversion coating produced on magnesium alloys in a boiling solution of sodium dichromate.
- **dielectric shield**
  - In a cathodic protection system, an electrically nonconductive material, such as a coating, plastic sheet, or pipe, that is placed between an anode and an adjacent cathode to avoid current wastage and to improve current distribution, usually on the cathode.
- **differential aeration cell**
  - An electrolytic cell , the electromotive force of which is due to a difference in air (oxygen) concentration at one electrode as compared with that at another electrode of the same material. See also concentration cell .
- **diffusion**
  - (1) Spreading of a constituent in a gas, liquid, or solid, tending to make the composition of all parts uniform. (2) The spontaneous movement of atoms or molecules to new sites within a material.
- **diffusion coating**
  - Any process whereby a base metal or alloy is either (1) coated with another metal or alloy and heated to a sufficient temperature in a suitable environment or (2) exposed to a gaseous or liquid medium containing the other metal or alloy, thus causing diffusion of the coating or of the other metal or alloy into the base metal with resultant changes in the composition and properties of its surface.
- **diffusion coefficient**
  - A factor of proportionality representing the amount of substance diffusing across a unit area through a unit concentration gradient in unit time.
- **diffusion-limited current density**
  - The current density , often referred to as limiting current density , that corresponds to the maximum transfer rate that a particular species can sustain because of the limitation of diffusion.
- **dimple rupture**
  - A fractographic term describing ductile fracture that occurs through the formation and coalescence of microvoids along the fracture path. The fracture surface of such a ductile fracture appears dimpled when observed at high magnification and usually is most clearly resolved when viewed in a scanning electron microscope.
- **disbondment**
  - The destruction of adhesion between a coating and the surface coated.
- **discontinuity**
  - Any interruption in the normal physical structure or configuration of a part, such as cracks, laps, seams, inclusions, or porosity. A discontinuity may or may not affect the usefulness of the part.
- **dislocation**
  - A linear imperfection in a crystalline array of atoms. Two basic types are recognized: (1) an edge dislocation corresponds to the row of mismatched atoms along the edge formed by an extra, partial plane of atoms within the body of a crystal; (2) a screw dislocation corresponds to the axis of a spiral structure in a crystal, characterized by a distortion that joins normally parallel planes together to form a continuous helical ramp (with a pitch of one interplanar distance) winding about the dislocation. Most prevalent is the so-called mixed dislocation, which is any combination of an edge dislocation and a screw dislocation.
- **double layer**
  - The interface between an electrode or a suspended particle and an electrolyte created by charge-charge interaction leading to an alignment of oppositely charged ions at the surface of the electrode or particle. The simplest model is represented by a parallel plate condensor.
- **drainage**
  - Conduction of electric current from an underground metallic structure by means of a metallic conductor. Forced drainage is that applied to underground metallic structures by means of an applied electromotive force or sacrificial anode. Natural drainage is that from an underground structure to a more negative (more anodic) structure, such as the negative bus of a trolley substation.

- **dry corrosion**
  - See gaseous corrosion .
- **drying oil**
  - An oil capable of conversion from a liquid to a solid by slow reaction with oxygen in the air.
- **ductile fracture**
  - Fracture characterized by tearing of metal accompanied by appreciable gross plastic deformation and expenditure of considerable energy. Contrast with brittle fracture .
- **ductility**
  - The ability of a material to deform plastically without fracturing, measured by elongation or reduction of area in a tensile test, by height of cupping in an Erichsen test, or by other means.
- **dummy cathode**
  - (1) A cathode , usually corrugated to give variable current densities, that is plated at low current densities to preferentially remove impurities from a plating solution. (2) A substitute cathode that is used during adjustment of operating conditions.
- **dummying**
  - Plating with dummy cathodes.
- **E**
- **885-°F (475-°C) embrittlement**
  - Embrittlement of stainless steels upon extended exposure to temperatures between 400 and 510 °C (750 and 950 °F). This type of embrittlement is caused by fine, chromium-rich precipitates that segregate at grain boundaries; time at temperature directly influences the amount of segregation. Grain-boundary segregation of the chromium-rich precipitates increases strength and hardness, decreases ductility and toughness, and changes corrosion resistance. This type of embrittlement can be reversed by heating above the precipitation range.
- **elastic deformation**
  - A change in dimensions directly proportional to and in phase with an increase or decrease in applied force.
- **elasticity**
  - The property of a material by virtue of which deformation caused by stress disappears upon removal of the stress. A perfectly elastic body completely recovers its original shape and dimensions after release of stress.
- **elastic limit**
  - The maximum stress that a material is capable of sustaining without any permanent strain (deformation) remaining upon complete release of the stress.
- **elastomer**
  - A natural or synthetic polymer, which at room temperature can be stretched repeatedly to at least twice its original length, and which after removal of the tensile load will immediately and forcibly return to approximately its original length.
- **electrical conductivity**
  - See conductivity .
- **electrical isolation**
  - The condition of being electrically separated from other metallic structures or the environment.
- **electrical resistivity**
  - The electrical resistance offered by a material to the flow of current, times the cross-sectional area of current flow and per unit length of current path; the reciprocal of the conductivity. Also called resistivity or specific resistance.
- **electrochemical admittance**
  - The inverse of electrochemical impedance .
- **electrochemical cell**
  - An electrochemical system consisting of an anode and a cathode in metallic contact and immersed in an electrolyte . (The anode and cathode may be different metals or dissimilar areas on the same metal surface.)
- **electrochemical corrosion**
  - Corrosion that is accompanied by a flow of electrons between cathodic and anodic areas on metallic surfaces.
- **electrochemical equivalent**
  - The weight of an element or group of elements oxidized or reduced at 100% efficiency by the passage of a unit quantity of electricity. Usually expressed as grams per coulomb.

- **electrochemical impedance**
  - The frequency-dependent complex-valued proportionality factor ($\Delta E/\Delta i$) between the applied potential or current and the response signal. This factor is the total opposition (Ω or $\Omega\cdot$ cm^2) of an electrochemical system to the passage of charge. The value is related to the corrosion rate under certain circumstances.
- **electrochemical potential**
  - The partial derivative of the total electrochemical free energy of a constituent with respect to the number of moles of this constituent where all factors are kept constant. It is analogous to the chemical potential of a constituent except that it includes the electric as well as chemical contributions to the free energy. The potential of an electrode in an electrolyte relative to a reference electrode measured under open circuit conditions.
- **electrochemical series**
  - Same as electromotive force series .
- **electrode**
  - (1) An electronic conductor used to establish electrical contact with an electrolytic part of a circuit. (2) An electronic conductor in contact with an ionic conductor.
- **electrode polarization**
  - Change of electrode potential with respect to a reference value. Often the free corrosion potential is used as the reference value. The change may be caused, for example, by the application of an external electrical current or by the addition of an oxidant or reductant.
- **electrodeposition**
  - The deposition of a substance on an electrode by passing electric current through an electrolyte .
- **electrode potential**
  - The potential of an electrode in an electrolyte as measured against a reference electrode . The electrode potential does not include any resistance losses in potential in either the solution or external circuit. It represents the reversible work to move a unit charge from the electrode surface through the solution to the reference electrode.
- **electrode reaction**
  - Interfacial reaction equivalent to a transfer of charge between electronic and ionic conductors. See also anodic reaction and cathodic reaction .
- **electrogalvanizing**
  - The electroplating of zinc upon iron or steel.
- **electrokinetic potential**
  - This potential , sometimes called zeta potential, is a potential difference in the solution caused by residual, unbalanced charge distribution in the adjoining solution, producing a double layer. The electrokinetic potential is different from the electrode potential in that it occurs exclusively in the solution phase; that is, it represents the reversible work necessary to bring unit charge from infinity in the solution up to the interface in question but not through the interface.
- **electroless plating**
  - A process in which metal ions in a dilute aqueous solution are plated out on a substrate by means of autocatalytic chemical reduction.
- **electrolysis**
  - Production of chemical changes of the electrolyte by the passage of current through an electrochemical cell .
- **electrolyte**
  - (1) A chemical substance or mixture, usually liquid, containing ions that migrate in an electric field. (2) A chemical compound or mixture of compounds which when molten or in solution will conduct an electric current.
- **electrolytic cell**
  - An assembly, consisting of a vessel, electrodes, and an electrolyte, in which electrolysis can be carried out.
- **electrolytic cleaning**
  - A process of removing soil, scale, or corrosion products from a metal surface by subjecting it as an electrode to an electric current in an electrolytic bath.
- **electrolytic protection**
  - See cathodic protection .
- **electromotive force**
  - Electrical potential; voltage.

- **electromotive force series (emf series)**
  - A list of elements arranged according to their standard electrode potentials, with "noble" metals such as gold being positive and "active" metals such as zinc being negative.
- **electron flow**
  - A movement of electrons in an external circuit an anode and cathode in a corrosion cell; the current flow is arbitrarily considered to be in an opposite direction to the electron flow.
- **electroplating**
  - Electrodepositing a metal or alloy in an adherent form on an object serving as a cathode .
- **electropolishing**
  - A technique commonly used to prepare metallographic specimens, in which a high polish is produced by making the specimen the anode in an electrolytic cell , where preferential dissolution at high points smooths the surface.
- **electrotinning**
  - Electroplating tin on object.
- **embrittlement**
  - The severe loss of ductility or toughness or both, of a material, usually a metal or alloy. Many forms of embrittlement can lead to brittle fracture . Many forms can occur during thermal treatment or elevated-temperature service (thermally induced embrittlement). Some of these forms of embrittlement, which affect steels, include blue brittleness , 885-°F (475-°C) embrittlement , quench-age embrittlement , sigma-phase embrittlement , strain-age embrittlement , temper embrittlement , tempered martensite embrittlement , and thermal embrittlement . In addition, steels and other metals and alloys can be embrittled by environmental conditions (environmentally assisted embrittlement). The forms of environmental embrittlement include acid embrittlement , caustic embrittlement , corrosion embrittlement , creep-rupture embrittlement , hydrogen embrittlement , liquid metal embrittlement , neutron embrittlement , solder embrittlement , solid metal embrittlement, and stress-corrosion cracking.
- **endurance limit**
  - The maximum stress that a material can withstand for an infinitely large number of fatigue cycles. See also fatigue strength .
- **environment**
  - The surroundings or conditions (physical, chemical, mechanical) in which a material exists.
- **environmental cracking**
  - Brittle fracture of a normally ductile material in which the corrosive effect of the environment is a causative factor. Environmental cracking is a general term that includes corrosion fatigue , high-temperature hydrogen attack , hydrogen blistering , hydrogen embrittlement , liquid metal embrittlement , solid metal embrittlement , stress-corrosion cracking , and sulfide stress cracking . The following terms have been used in the past in connection with environment cracking, but are becoming obsolete: caustic embrittlement, delayed fracture, season cracking, static fatigue, stepwise cracking, sulfide corrosion cracking, and sulfide stress-corrosion cracking. See also embrittlement .
- **environmentally assisted embrittlement**
  - See embrittlement .
- **epoxy**
  - Resin formed by the reaction of bisphenol and epichlorohydrin.
- **equilibrium (reversible) potential**
  - The potential of an electrode in an electrolytic solution when the forward rate of a given reaction is exactly equal to the reverse rate. The equilibrium potential can only be defined with respect to a specific electrochemical reaction.
- **erosion**
  - Destruction of metals or other materials by the abrasive action of moving fluids, usually accelerated by the presence of solid particles or matter in suspension. When corrosion occurs simultaneously, the term erosion-corrosion is often used.
- **erosion-corrosion**
  - A conjoint action involving corrosion and erosion in the presence of a moving corrosive fluid, leading to the accelerated loss of material.
- **eutectic**
  - (1) An isothermal reversible reaction in which a liquid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of

components in the system. (2) An alloy having the composition indicated by the eutectic point on an equilibrium diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectic reaction.

- **eutectoid**
  - (1) An isothermal reversible reaction in which a solid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having the composition indicated by the eutectoid point on an equilibrium diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectoid reaction.
- **exchange current**
  - When an electrode reaches dynamic equilibrium in a solution, the rate of anodic dissolution balances the rate of cathodic plating. The rate at which either positive or negative charges are entering or leaving the surface at this point is known as the exchange current.
- **exchange current density**
  - The rate of charge transfer per unit area when an electrode reaches dynamic equilibrium (at its reversible potential) in a solution; that is, the rate of anodic charge transfer (oxidation) balances the rate of cathodic charge transfer (reduction).
- **exfoliation**
  - Corrosion that proceeds laterally from the sites of initiation along planes parallel to the surface, generally at grain boundaries, forming corrosion products that force metal away from the body of the material, giving rise to a layered appearance.
- **external circuit**
  - The wires, connectors, measuring devices, current sources, etc., that are used to bring about or measure the desired electrical conditions within the test cell. It is this portion of the cell through which electrons travel.
- **F**
- **failure**
  - A general term used to imply that a part in service (1) has become completely inoperable, (2) is still operable but is incapable of satisfactorily performing its intended function, or (3) has deteriorated seriously, to the point that it has become unreliable or unsafe for continued use.
- **Faraday's law**
  - (1) The amount of any substance dissolved or deposited in electrolysis is proportional to the total electric charge passed. (2) The amounts of different substances dissolved or deposited by the passage of the same electric charge are proportional to their equivalent weights.
- **fatigue**
  - The phenomenon leading to fracture under repeated or fluctuating stresses having a maximum value less than the tensile strength of the material. Fatigue fractures are progressive and grow under the action of the fluctuating stress.
- **fatigue crack growth rate,**
  - *da*/*dN*. The rate of crack extension caused by constant-amplitude fatigue loading, expressed in terms of crack extension per cycle of load application.
- **fatigue life**
  - The number of cycles of stress that can be sustained prior to failure under a stated test condition.
- **fatigue limit**
  - The maximum stress that presumably leads to fatigue fracture in a specified number of stress cycles. If the stress is not completely reversed, the value of the mean stress, the minimum stress, or the stress ratio should also be stated. Compare with endurance limit .
- **fatigue strength**
  - The maximum stress that can be sustained for a specified number of cycles without failure, the stress being completely reversed within each cycle unless otherwise stated.
- **ferrite**
  - (1) A solid solution of one or more elements in body-centered cubic iron. Unless otherwise designated (for instance, as chromium ferrite), the solute is generally assumed to be carbon. On some equilibrium diagrams, there are two ferrite regions separated by an austenite area. The lower area is alpha ferrite; the upper, delta ferrite. If there is no designation, alpha ferrite is assumed. (2) In the field of magnetics, substances having the general formula: $M^{2+}O \cdot M_2^{3+}O_3$, the trivalent metal often being iron.
- **filiform corrosion**

- Corrosion that occurs under some coatings in the form of randomly distributed threadlike filaments.

- **film**
  - A thin, not necessarily visible, layer of material.
- **fish eyes**
  - Areas on a steel fracture surface having a characteristic white crystalline appearance.
- **flakes**
  - Short, discontinuous internal fissures in wrought metals attributed to stresses produced by localized transformation and decreased solubility of hydrogen during cooling after hot working. In a fracture surface, flakes appear as bright silvery areas; on an etched surface, they appear as short, discontinuous cracks. Also called shatter cracks or snowflakes.
- **flame spraying**
  - Thermal spraying in which a coating material is fed into an oxyfuel gas flame, where it is melted. Compressed gas may or may not be used to atomize the coating material and propel it onto the substrate.
- **foreign structure**
  - Any metallic structure that is not intended as part of a cathodic protection system of interest.
- **fouling**
  - An accumulation of deposits. This term includes accumulation and growth of marine organisms on a submerged metal surface and also includes the accumulation of deposits (usually inorganic) on heat exchanger tubing.
- **fouling organism**
  - Any aquatic organism with a sessile adult stage that attaches to and fouls underwater structures of ships.
- **fractography**
  - Descriptive treatment of fracture, especially in metals, with specific reference to photographs of the fracture surface. Macrofractography involves photographs at low magnification (<25×); microfractography, photographs at high magnification (>25×).
- **fracture mechanics**
  - A quantitative analysis for evaluating structural behavior in terms of applied stress, crack length, and specimen or machine component geometry. See also linear elastic fracture mechanics .
- **fracture toughness**
  - A generic term for measures or resistance to extension of a crack. The term is sometimes restricted to results of fracture mechanics tests, which are directly applicable in fracture control. However, the term commonly includes results from simple tests of notched or precracked specimens not based on fracture mechanics analysis. Results from test of the latter type are often useful for fracture control, based on either service experience or empirical correlations with fracture mechanics tests. See also stress-intensity factor .
- **free carbon**
  - The part of the total carbon in steel or cast iron that is present in elemental form as graphite or temper carbon. Contrast with combined carbon .
- **free corrosion potential**
  - Corrosion potential in the absence of net electrical current flowing to or from the metal surface.
- **free ferrite**
  - Ferrite that is formed directly from the decomposition of hypoeutectoid austenite during cooling, without the simultaneous formation of cementite. Also called proeutectoid ferrite.
- **free machining**
  - Pertains to the machining characteristics of an alloy to which one or more ingredients have been introduced to give small broken chips, lower power consumption, better surface finish, and longer tool life; among such additions are sulfur or lead to steel, lead to brass, lead and bismuth to aluminum, and sulfur or selenium to stainless steel.
- **fretting**
  - A type of wear that occurs between tight-fitting surfaces subjected to cyclic relative motion of extremely small amplitude. Usually, fretting is accompanied by corrosion, especially of the very fine wear debris.
- **fretting corrosion**
  - The accelerated deterioration at the interface between contacting surfaces as the result of corrosion and slight oscillatory movement between the two surfaces.

- **furan**
  - Resin formed from reactions involving furfuryl alcohol alone or in combination with other constituents.
- **G**
- **galvanic anode**
  - A metal which, because of its relative position in the galvanic series, provides sacrificial protection to metals that are more noble in the series, when coupled in an electrolyte.
- **galvanic cell**
  - A cell in which chemical change is the source of electrical energy. It usually consists of two dissimilar conductors in contact with each other and with an electrolyte, or of two similar conductors in contact with each other and with dissimilar electrolytes.
- **galvanic corrosion**
  - Accelerated corrosion of a metal because of an electrical contact with a more noble metal or nonmetallic conductor in a corrosive electrolyte.
- **galvanic couple**
  - A pair of dissimilar conductors, commonly metals, in electrical contact. See also galvanic corrosion .
- **galvanic couple potential**
  - See mixed potential .
- **galvanic current**
  - The electric current that flows between metals or conductive nonmetals in a galvanic couple .
- **galvanic series**
  - A list of metals and alloys arranged according to their relative corrosion potentials in a given environment. Compare with electromotive force series .
- **galvanize**
  - To coat a metal surface with zinc using any of various processes.
- **galvanneal**
  - To produce a zinc-iron alloy coating on iron or steel by keeping the coating molten after hot dip galvanizing until the zinc alloys completely with the base metal.
- **galvanometer**
  - An instrument for indicating or measuring a small electric current by means of a mechanical motion derived from electromagnetic or electrodynamic forces produced by the current.
- **galvanostatic**
  - An experimental technique whereby an electrode is maintained at a constant current in an electrolyte .
- **gaseous corrosion**
  - Corrosion with gas as the only corrosive agent and without any aqueous phase on the surface of the metal. Also called dry corrosion.
- **gamma iron**
  - The face-centered cubic form of pure iron, stable from 910 to 1400 °C (1670 to 2550 °F).
- **general corrosion**
  - See uniform corrosion .
- **Gibbs free energy**
  - The thermodynamic function $\Delta G = \Delta H - T\Delta S$ where H is enthalpy, T is absolute temperature, and S is entropy. Also called free energy, free enthalpy, or Gibbs function.
- **glass electrode**
  - A glass membrane electrode used to measure pH or hydrogen-ion activity.
- **grain**
  - An individual crystal in a polycrystalline metal or alloy; it may or may not contain twinned regions and subgrains.
- **grain boundary**
  - A narrow zone in a metal corresponding to the transition from one crystallographic orientation to another, thus separating one grain from another; the atoms in each grain are arranged in an orderly pattern.
- **grain-boundary corrosion**
  - Same as intergranular corrosion. See also interdendritic corrosion .
- **graphitic corrosion**

- Deterioration of gray cast iron in which the metallic constituents are selectively leached or converted to corrosion products leaving the graphite intact. The term graphitization is commonly used to identify this form of corrosion, but is not recommended because of its use in metallurgy for the decomposition of carbide to graphite. See also dealloying and selective leaching .

- **graphitization**
  - A metallurgical term describing the formation of graphite in iron or steel, usually from decomposition of iron carbide at elevated temperatures. Not recommended as a term to describe graphitic corrosion .
- **green liquor**
  - The liquor resulting from dissolving molten smelt from the kraft recovery furnace in water. See also kraft process and smelt .
- **groundbed**
  - A buried item, such as junk steel or graphite rods, that serves as the anode for the cathodic protection of pipelines or other buried structures. See also deep groundbed .
- **H**
- **half cell**
  - An electrode immersed in a suitable electrolyte , designed for measurements of electrode potential .
- **halogen**
  - Any of the elements of the halogen family, consisting of fluorine, chlorine, bromine, iodine, and astatine.
- **hard chromium**
  - Chromium plated for engineering rather than decorative applications.
- **hardenability**
  - The relative ability of a ferrous alloy to form martensite when quenched from a temperature above the upper critical temperature. Hardenability is commonly measured as the distance below a quenched surface at which the metal exhibits a specific hardness (50 HRC, for example) or a specific percentage of martensite in the microstructure.
- **hardfacing**
  - Depositing filler metal on a surface by welding, spraying, or braze welding to increase resistance to abrasion, erosion, wear, galling, impact, or cavitation damage.
- **hard water**
  - Water that contains certain salts, such as those of calcium or magnesium, which form insoluble deposits in boilers and from precipitates with soap.
- **heat-affected zone**
  - That portion of the base metal that was not melted during brazing, cutting, or welding, but whose microstructure and mechanical properties were altered by the heat.
- **heat check**
  - A patter of parallel surface cracks that are formed by alternate rapid heating and cooling of the extreme surface metal, sometimes found on forging dies and piercing punches. There may be two sets of parallel cracks, one set perpendicular to the other.
- **hematite**
  - (1) An iron mineral crystallizing in the rhombohedral system; the most important ore or iron. (2) An iron oxide, Fe_2O_3, corresponding to an iron content of approximately 70%.
- **high-temperature hydrogen attack**
  - A loss of strength and ductility of steel by high-temperature reaction of absorbed hydrogen with carbides in the steel resulting in decarburization and internal fissuring.
- **holidays**
  - Discontinuities in a coating (such as porosity, cracks, gaps, and similar flaws) that allow areas of base metal to be exposed to any corrosive environment that contacts the coated surface.
- **hot corrosion**
  - An accelerated corrosion of metal surfaces that results from the combined effect of oxidation and reactions with sulfur compounds and other contaminants, such as chlorides, to form a molten salt on a metal surface that fluxes, destroys, or disrupts the normal protective oxide. See also gaseous corrosion .
- **hot cracking**
  - Also called solidification cracking, hot cracking of weldments is caused by the segregation at grain boundaries of low-melting constituents in the weld metal. This can result in grain-boundary

tearing under thermal contraction stresses. Hot cracking can be minimized by the use of low-impurity welding materials and proper joint design. See also cold cracking , lamellar tearing , and stress-relief cracking .

- **hot working**
  - Deforming metal plastically at such a temperature and strain rate that recrystallization takes place simultaneously with the deformation, thus avoiding any strain hardening. Contrast with cold working .
- **hot dip coating**
  - A metallic coating obtained by dipping the base metal into a molten metal.
- **hot shortness**
  - A tendency for some alloys to separate along grain boundaries when stressed or deformed at temperatures near the melting point. Hot shortness is caused by a low-melting constituent, often present only in minute amounts, that is segregated at grain boundaries.
- **humidity tests**
  - A corrosion test involving exposure of specimens at controlled levels of humidity and temperature. Contrast with salt-fog test.
- **hydrogen-assisted cracking (HAC)**
  - See hydrogen embrittlement .
- **hydrogen-assisted stress-corrosion cracking (HSCC)**
  - See hydrogen embrittlement .
- **hydrogen blistering**
  - The formation of blisters on or below a metal surface from excessive internal hydrogen pressure. Hydrogen may be formed during cleaning, plating, corrosion, and so forth.
- **hydrogen damage**
  - A general term for the embrittlement, cracking, blistering, and hydride formation that can occur when hydrogen is present in some metals.
- **hydrogen embrittlement**
  - A process resulting in decrease of the toughness or ductility of a metal due to the presence of atomic hydrogen. Hydrogen embrittlement has been recognized classically as being of two types. The first, known as internal hydrogen embrittlement, occurs when the hydrogen enters molten metal which becomes supersaturated with hydrogen immediately after solidification. The second type, environmental hydrogen embrittlement, results from hydrogen being absorbed by solid metals. This can occur during elevated-temperature thermal treatments and in service during electroplating, contact with maintenance chemicals, corrosion reactions, cathodic protection, and operating in high-pressure hydrogen. In the absence of residual stress or external loading, environmental hydrogen embrittlement is manifested in various forms, such as blistering, internal cracking, hydride formation, and reduced ductility. With a tensile stress or stress-intensity factor exceeding a specific threshold, the atomic hydrogen interacts with the metal to induce subcritical crack growth leading to fracture. In the absence of a corrosion reaction (polarized cathodically), the usual term used is hydrogen-assisted cracking (HAC) or hydrogen stress cracking (HSC). In the presence of active corrosion, usually as pits or crevices (polarized anodically), the cracking is generally called stress-corrosion cracking (SCC), but should more properly be called hydrogen-assisted stress-corrosion cracking (HSCC). Thus, HSC and electrochemically anodic SCC can operate separately or in combination (HSCC). In some metals, such as high-strength steels, the mechanism is believed to be all, or nearly all, HSC. The participating mechanism of HSC is not always recognized and may be evaluated under the generic heading of SCC.
- **hydrogen-induced cracking (HIC)**
  - Same as hydrogen embrittlement .
- **hydrogen overvoltage**
  - Overvoltage associated with the liberation of hydrogen gas.
- **hydrogen stress cracking (HSC)**
  - See hydrogen embrittlement .
- **hydrolysis**
  - (1) Decomposition or alteration of a chemical substance by water. (2) In aqueous solutions of electrolytes, the reactions of cations with water to produce a weak base or of anions to produce a weak acid.
- **hydrophilic**
  - Having an affinity for water. Contrast with hydrophobic .

- **hydrophobic**
  - Lacking an affinity for, repelling, or failing to absorb or adsorb water. Contrast with hydrophilic .
- **hygroscopic**
  - (1) Possessing a marked ability to accelerate the condensation of water vapor; applied to condensation nuclei composed of salts that yield aqueous solutions of a very low equilibrium vapor pressure compared with that of pure water at the same temperature. (2) Pertaining to a substance whose physical characteristics are appreciably altered by effects of water vapor. (3) Pertaining to water absorbed by dry soil minerals from the atmosphere; the amounts depend on the physicochemical character of the surfaces, and increase with rising relative humidity.
- **I**
- **immersion plating**
  - Depositing a metallic coating on a metal immersed in a liquid solution, without the aid of an external electric current. Also called dip plating.
- **immunity**
  - A state of resistance to corrosion or anodic dissolution of a metal caused by thermodynamic stability of the metal.
- **impingement corrosion**
  - A form of erosion-corrosion generally associated with the local impingement of a high-velocity, flowing fluid against a solid surface.
- **impressed current**
  - Direct current supplied by a device employing a power source external to the electrode system of a cathodic protection installation.
- **inclusions**
  - Particles of foreign material in a metallic matrix. The particles are usually compounds (such as oxides, sulfides, or silicates), but may be of any substance that is foreign to (and essentially insoluble in) the matrix.
- **incubation period**
  - A period prior to the detection of corrosion while the metal is in contact with a corrodent.
- **industrial atmosphere**
  - An atmosphere in an area of heavy industry with soot, fly ash, and sulfur compounds as the principal constituents.
- **inert anode**
  - An anode that is insoluble in the electrolyte under the conditions prevailing in the electrolysis .
- **inhibitor**
  - A chemical substance or combination of substances that, when present in the environment, prevents or reduces corrosion without significant reaction with the components of the environment.
- **inorganic**
  - Being or composed of matter other than hydrocarbons and their derivatives, or matter that is not of plant or animal origin. Contrast with organic .
- **inorganic zinc-rich paint**
  - Coating containing a zinc powder pigment in an inorganic vehicle.
- **intensiostatic**
  - See galvanostatic .
- **intercrystalline corrosion**
  - See intergranular corrosion .
- **intercrystalline cracking**
  - See intergranular cracking .
- **interdendritic corrosion**
  - Corrosive attack that progresses preferentially along interdendritic paths. This type of attack results from local differences in composition, such as coring commonly encountered in alloy castings.
- **intergranular**
  - Between crystals or grains. Also called intercrystalline. Contrast with transgranular .
- **intergranular corrosion**
  - Corrosion occurring preferentially at grain boundaries, usually with slight or negligible attack on the adjacent grains. Also called intercrystalline corrosion.
- **intergranular cracking**

    - Cracking or fracturing that occurs between the grains or crystals in a polycrystalline aggregate. Also called intercrystalline cracking. Contrast with transgranular cracking .
- **intergranular fracture**
    - Brittle fracture of a metal in which the fracture is between the grains, or crystals, that form the metal. Also called intercrystalline fracture. Contrast with transgranular fracture .
- **intergranular stress-corrosion cracking (IGSCC)**
    - Stress-corrosion cracking in which the cracking occurs along grain boundaries.
- **intermediate electrode**
    - Same as bipolar electrode .
- **internal oxidation**
    - The formation of isolated particles of corrosion products beneath the metal surface. This occurs as the result of preferential oxidation of certain alloy constituents by inward diffusion of oxygen, nitrogen, sulfur, and so forth.
- **intumescence**
    - The swelling or bubbling of a coating usually because of heating (term currently used in space and fire protection applications).
- **ion**
    - An atom, or group of atoms, that has gained or lost one or more outer electrons and thus carries an electric charge. Positive ions, or cations, are deficient in outer electrons. Negative ions, or anions, have an excess of outer electrons.
- **ion exchange**
    - The reversible interchange of ions between a liquid and solid, with no substantial structural changes in the solid.
- **iron rot**
    - Deterioration of wood in contact with iron-based alloys.
- **isocorrosion diagram**
    - A graph or chart that shows constant corrosion behavior with changing solution (environment) composition and temperature.
- **K**
- ***K***
    - $_{ISCC}$. Abbreviation for the critical value of the plane strain stress-intensity factor that will produce crack propagation by stress-corrosion cracking of a given material in a given environment.
- **knife-line attack**
    - Intergranular corrosion of an alloy, usually stabilized stainless steel, along a line adjoining or in contact with a weld after heating into the sensitization temperature range.
- **kraft process**
    - A wood-pulping process in which sodium sulfate is used in the caustic soda pulp-digestion liquor. Also called kraft pulping or sulfate pulping.
- **L**
- **lamellar corrosion**
    - See exfoliation corrosion.
- **lamellar tearing**
    - Occurs in the base metal adjacent to weldments due to high through-thickness strains introduced by weld metal shrinkage in highly restrained joints. Tearing occurs by decohesion and linking along the working direction of the base metal; cracks usually run roughly parallel to the fusion line and are steplike in appearance. Lamellar tearing can be minimized by designing joints to minimize weld shrinkage stresses and joint restraint. See also cold cracking , hot cracking , and stress-relief cracking .
- **Langelier saturation index**
    - An index calculated from total dissolved solids, calcium concentration, total alkalinity, pH, and solution temperature that shows the tendency of a water solution to precipitate or dissolve calcium carbonate.
- **ledeburite**
    - The eutectic of the iron-carbon system, the constituents of which are austenite and cementite . The austenite decomposes into ferrite and cementite on cooling below Ar_1, the temperature at which transformation of austenite to ferrite or ferrite plus cementite is completed during cooling.
- **ligand**
    - The molecule, ion, or group bound to the central atom in a chelate or a coordination compound .

- **limiting current density**
  - The maximum current density that can be used to obtain a desired electrode reaction without undue interference such as from polarization .
- **linear elastic fracture mechanics**
  - A method of fracture analysis that can determine the stress (or load) required to induce fracture instability in a structure containing a cracklike flaw of known size and shape. See also fracture mechanics and stress-intensity factor .
- **lipophilic**
  - Having an affinity for oil. See also hydrophilic and hydrophobic .
- **liquid metal embrittlement**
  - Catastrophic brittle failure of a normally ductile metal when in contact with a liquid metal and subsequently stressed in tension.
- **local action**
  - Corrosion due to the action of "local cells," that is, galvanic cells resulting from inhomogeneities between adjacent areas on a metal surface exposed to an electrolyte .
- **local cell**
  - A galvanic cell resulting from inhomogeneities between areas on a metal surface in an electrolyte . The inhomogeneities may be of physical or chemical nature in either the metal or its environment.
- **localized corrosion**
  - Corrosion at discrete sites, for example, crevice corrosion , pitting , and stress-corrosion cracking.
- **long-line current**
  - Current that flows through the earth from an anodic to a cathodic area of a continuous metallic structure. Usually used only where the areas are separated by considerable distance and where the current results from concentration-cell action.
- **luggin probe**
  - A small tube or capillary filled with electrolyte, terminating close to the metal surface under study, and used to provide an ionically conducting path without diffusion between an electrode under study and a reference electrode .
- **M**
- **macroscopic**
  - Visible at magnifications to 25×.
- **macrostructure**
  - The structure of metals as revealed by macroscopic examination of the etched surface of a polished specimen.
- **magnetite**
  - Naturally occurring magnetic oxide of iron (Fe_3O_4).
- **martensite**
  - A generic term for microstructures formed by diffusionless phase transformation in which the parent and product phases have a specific crystallographic relationship. Martensite is characterized by an acicular pattern in the microstructure in both ferrous and nonferrous alloys. In alloys where the solute atoms occupy interstitial positions in the martensitic lattice (such as carbon in iron), the structure is hard and highly strained; but where the solute atoms occupy substitutional positions (such as nickel in iron), the martensite is soft and ductile. The amount of high-temperature phase that transforms to martensite on cooling depends to a large extent on the lowest temperature attained, there being a rather distinct beginning temperature (M_s) and a temperature at which the transformation is essentially complete (M_f).
- **mechanical plating**
  - Plating wherein fine metal powders are peened onto the work by tumbling or other means.
- **metal dusting**
  - Accelerated deterioration of metals in carbonaceous gases at elevated temperatures to form a dustlike corrosion product.
- **metallic glass**
  - An alloy having an amorphous or glassy structure. See also amorphous solid .
- **metallizing**
  - (1) The application of an electrically conductive metallic layer to the surface of nonconductors. (2) The application of metallic coatings by nonelectrolytic procedures such as spraying of molten metal and deposition from the vapor phase.

- **microbial corrosion**
  - See biological corrosion .
- **microscopic**
  - Visible at magnifications above 25×.
- **microstructure**
  - The structure of a prepared surface of a metal as revealed by a microscope at a magnification exceeding 25×.
- **mill scale**
  - The heavy oxide layer formed during hot fabrication or heat treatment of metals.
- **mixed potential**
  - The potential of a specimen (or specimens in a galvanic couple) when two or more electrochemical reactions are occurring. Also called galvanic couple potential.
- **molal solution**
  - Concentration of a solution expressed in moles of solute divided by 1000 g of solvent.
- **molar solution**
  - Aqueous solution that contains 1 mole (gram-molecular weight) of solute in 1 L of the solution.
- **mole**
  - One mole is the mass numerically equal (in grams) to the relative molecular mass of a substance. It is the amount of substance of a system that contains as many elementary units (6.02×10^{23}) as there are atoms of carbon in 0.012 kg of the pure nuclide ^{12}C; the elementary unit must be specified and may be an atom, molecule, ion, electron, photon, or even a specified group of such units.
- **monomer**
  - A molecule, usually an organic compound, having the ability to join with a number of identical molecules to form a polymer .
- **N**
- **natural aging**
  - Spontaneous aging of a supersaturated solid solution at room temperature. See also aging . Compare with artificial aging .
- **Nernst equation**
  - An equation that expresses the exact electromotive force of a cell in terms of the activities of products and reactants of the cell.
- **Nernst layer, Nernst thickness**
  - The diffusion layer or the hypothetical thickness of this layer as given by the theory of Nernst. It is defined by: $i_d = nFD[(C_o - C)/\delta]$, where i_d is the diffusion-limited current density, D is the diffusion coefficient, C_o is the concentration at the electrode surface, and δ is the Nernst thickness (0.5 mm in many cases of unstirred aqueous electrolytes).
- **neutron embrittlement**
  - Embrittlement resulting from bombardment with neutrons, usually encountered in metals that have been exposed to a neutron flux in the core of a reactor. In steels, neutron embrittlement is evidenced by a rise in the ductile-to-brittle transition temperature.
- **nitriding**
  - Introducing nitrogen into the surface layer of a solid ferrous alloy by holding at a suitable temperature (below Ac_1 for ferritic steels) in contact with a nitrogenous material, usually ammonia or molten cyanide of appropriate composition. Quenching is not required to produce a hard case.
- **nitrocarburizing**
  - Any of several processes in which both nitrogen and carbon are absorbed into the surface layers of a ferrous material at temperatures below the lower critical temperature and, by diffusion, create a concentration gradient. Nitrocarburizing is performed primarily to provide an antiscuffing surface layer and to improve fatigue resistance. Compare with carbonitriding .
- **noble**
  - The positive direction of electrode potential , thus resembling noble metals such as gold and platinum.
- **noble metal**
  - (1) A metal whose potential is highly positive relative to the hydrogen electrode. (2) A metal with marked resistance to chemical reaction, particularly to oxidation and to solution by inorganic acids. The term as often used is synonymous with precious metal .

- **noble potential**
  - A potential more cathodic (positive) than the standard hydrogen potential.
- **normalizing**
  - Heating a ferrous alloy to a suitable temperature above the transformation range and then cooling in air to a temperature substantially below the transformation range.
- **normal solution**
  - An aqueous solution containing one gram equivalent of the active reagent in 1 L of the solution.
- **normal stress**
  - The stress component perpendicular to a plane on which forces act. Normal stress may be either tensile or compressive.
- **O**
- **open-circuit potential**
  - The potential of an electrode measured with respect to a reference electrode or another electrode when no current flows to or from it.
- **organic**
  - Being or composed of hydrocarbons or their derivatives, or matter of plant or animal origin. Contrast with inorganic .
- **organic acid**
  - A chemical compound with one or more carboxyl radicals (COOH) in its structure; examples are butyric acid, $CH_3(CH_2)_2COOH$; maleic acid, HOOCCH-CHCOOH; and benzoic acid, C_6H_5COOH.
- **organic zinc-rich paint**
  - Coating containing zinc powder pigment and an organic resin.
- **overaging**
  - Aging under conditions of time and temperature greater than those required to obtain maximum change in a certain property, so that the property is altered in the direction of the initial value.
- **overheating**
  - Heating a metal or alloy to such a high temperature that its properties are impaired. When the original properties cannot be restored by further heat treating, by mechanical working, or by a combination of working and heat treating, the overheating is known as burning .
- **overvoltage**
  - The difference between the actual electrode potential when appreciable electrolysis begins and the reversible electrode potential.
- **oxidation**
  - (1) A reaction in which there is an increase in valence resulting from a loss of electrons. Contrast with reduction . (2) A corrosion reaction in which the corroded metal forms an oxide; usually applied to reaction with a gas containing elemental oxygen, such as air.
- **oxidized surface (on steel)**
  - Surface having a thin, tightly adhering, oxidized skin (from straw to blue in color), extending in from the edge of a coil or sheet.
- **oxidizing agent**
  - A compound that causes oxidation , thereby itself being reduced.
- **oxygen concentration cell**
  - See differential aeration cell
- **ozone**
  - A powerfully oxidizing allotropic form of the element oxygen. The ozone molecule contains three atoms (O_3). Ozone gas is decidedly blue, both liquid and solid ozone are an opaque blue-black color, similar to that ink.
- **P**
- **partial annealing**
  - An imprecise term used to denote a treatment given cold-worked material to reduce its strength to controlled level or to effect stress relief. To be meaningful, the type of material, degree of cold work, and the time-temperature schedule must be stated.
- **parting**
  - See dealloying .
- **parts per billion**
  - A measure of proportion by weight, equivalent to one unit weight of a material per billion (10^9) unit weights of compound. One part per billion is equivalent to 1 mg/g.

- **parts per million**
  - A measure of proportion by weight, equivalent to one unit weight of a material per million (10^6) unit weights of compound. One part per million is equivalent to 1 mg/g.
- **passivation**
  - (1) A reduction of the anodic reaction rate of an electrode involved in corrosion. (2) The process in metal corrosion by which metals become passive . (3) The changing of a chemically active surface of a metal to a much less reactive state. Contrast with activation .
- **passivator**
  - A type of inhibitor that appreciably changes the potential of a metal to a more noble (positive) value.
- **passive**
  - (1) A metal corroding under the control of surface reaction product. (2) The state of the metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal.
- **passive-active cell**
  - A corrosion cell in which the anode is a metal in the active state and the cathode is the same metal in the passive state.
- **passivity**
  - A condition in which a piece of metal, because of an impervious covering of oxide or other compound, has a potential much more positive than that of the metal in the active state.
- **patina**
  - The coating, usually green, that forms on the surface of metals such as copper and copper alloys exposed to the atmosphere. Also used to describe the appearance of a weathered surface of any metal.
- **pearlite**
  - A metastable lamellar aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures above the bainite range.
- **phosphating**
  - Forming an adherent phosphate coating on a metal by immersion in a suitable aqueous phosphate solution. Also called phosphatizing. See also conversion coating .
- **pH**
  - The negative logarithm of the hydrogen-ion activity; it denotes the degree of acidity or basicity of a solution. At 25 °C (77 °F), 7.0 is the neutral value. Decreasing values below 7.0 indicate increasing acidity; increasing values above 7.0, increasing basicity.
- **physical vapor deposition**
  - A coating process whereby the cleaned and masked component to be coated is heated and rotated on a spindle above the streaming vapor generated by melting and evaporating a coating material source bar with a focused electron beam in an evacuated chamber.
- **physisorption**
  - The binding of an adsorbate to the surface of a solid by forces whose energy levels approximate those of condensation. Contrast with chemisorption .
- **pickle**
  - A solution or process used to loosen or remove corrosion products such as scale or tarnish.
- **pickling**
  - Removing surface oxides from metals by chemical or electrochemical reaction.
- **pitting**
  - Localized corrosion of a metal surface, confined to a point or small area, that takes the form of cavities.
- **pitting factor**
  - Ratio of the depth of the deepest pit resulting from corrosion divided by the average penetration as calculated from weight loss.
- **plane strain**
  - The stress condition in linear elastic fracture mechanics in which there is zero strain in a direction normal to both the axis of applied tensile stress and the direction of crack growth (that is, parallel to the crack front); most nearly achieved in loading thick plates along a direction parallel to the plate surface. Under plane-strain conditions, the plane of fracture instability is normal to the axis of the principal tensile stress.
- **plane stress**

- The stress condition in linear elastic fracture mechanics in which the stress in the thickness direction is zero; most nearly achieved in loading very thin sheet along a direction parallel to the surface of the sheet. Under plane-stress conditions, the plane of fracture instability is inclined 45° to the axis of the principal tensile stress.

- **plasma spraying**
  - A thermal spraying process in which the coating material is melted with heat from a plasma torch that generates a nontransferred arc; molten coating material is propelled against the base metal by the hot, ionized gas issuing from the torch.
- **plastic deformation**
  - The permanent (inelastic) distortion of metals under applied stresses that strain the material beyond its elastic limit .
- **plasticity**
  - The property that enables a material to undergo permanent deformation without rupture.
- **polarization**
  - (1) The change from the open-circuit electrode potential as the result of the passage of current. (2) A change in the potential of an electrode during electrolysis, such that the potential of an anode becomes more noble, and that of cathode more active, than their respective reversible potentials. Often accomplished by formation of a film on the electrode surface.
- **polarization admittance**
  - The reciprocal of polarization resistance (di/dE).
- **polarization curve**
  - A plot of current density versus electrode potential for a specific electrode-electrolyte combination.
- **polarization resistance**
  - The slope (dE/di) at the corrosion potential of a potential (E)/current density (i) curve. Also used to describe the method of measuring corrosion rates using this slopes.
- **polyester**
  - Resin formed by condensation of polybasic and monobasic acids with polyhydric alcohols.
- **polymer**
  - A chain of organic molecules produced by the joining of primary units called monomers.
- **potential**
  - Any of various functions from which intensity or velocity at any point in a field may be calculated. The driving influence of an electrochemical reaction. See also active potential , chemical potential , corrosion potential , critical pitting potential , decomposition potential , electrochemical potential , electrode potential , electrokinetic potential , equilibrium (reversible) potential , free corrosion potential , noble potential , open-circuit potential , protective potential , redox potential ,and standard electrode potential .
- **potential-pH diagram**
  - See Pourbaix (potential-pH) diagram .
- **potentiodynamic (potentiokinetic)**
  - The technique for varying the potential of an electrode in a continuous manner at preset rate.
- **potentiostat**
  - An instrument for automatically maintaining an electrode in an electrolyte at a constant potential or controlled potentials with respect to a suitable reference electrode.
- **potentiostatic**
  - The technique for maintaining a constant electrode potential .
- **poultice corrosion**
  - A term used in the automotive industry to describe the corrosion of vehicle body parts due to the collection of road salts and debris on ledges and in pockets that are kept moist by weather and washing. Also called deposit corrosion or attack.
- **Pourbaix (potential-pH) diagram**
  - A plot of the redox potential of a corroding system versus the pH of the system, compiled using thermodynamic data and the Nernst equation . The diagram shows regions within which the metal itself or some of its compounds are stable.
- **powder metallurgy**
  - The art of producing metal powders and utilizing metal powders for production of massive materials and shaped objects.
- **precious metal**

- One of the relatively scarce and valuable metals: gold, silver, and the platinum-group metals. Also called noble metal(s).
- **precipitation hardening**
  - Hardening caused by the precipitation of a constituent from a supersaturated solid solution. See also age hardening and aging .
- **precipitation heat treatment**
  - Artificial aging in which a constituent precipitates from a supersaturated solid solution.
- **precracked specimen**
  - A specimen that is notched and subjected to alternating stresses until a crack has developed at the root of the notch.
- **primary current distribution**
  - The current distribution in an electrolytic cell that is free of polarization .
- **primary passive potential (passivation potential)**
  - The potential corresponding to the maximum active current density (critical anodic current density) of an electrode that exhibits active-passive corrosion behavior.
- **primer**
  - The first coat of paint applied to a surface. Formulated to have good bonding and wetting characteristics; may or may not contain inhibiting pigments.
- **principal stress (normal)**
  - The maximum or minimum value of the normal stress at a point in a plane considered with the respect to all possible orientations of the considered plane. On such principal planes the shear stress is zero. There are three principal stresses on three mutually perpendicular planes. The state of stress at a point may be (1) uniaxial, a state of stress in which two of the three principal stresses are zero, (2) biaxial, a state of stress in which only one of the three principal stresses is zero, and (3) triaxial, a state of stress in which none of the principal stresses is zero. Multiaxial stress refers to either biaxial or triaxial stress.
- **profile**
  - Anchor pattern on a surface produced by abrasive blasting or acid treatment.
- **protective potential**
  - The threshold value of the corrosion potential that has to be reached to enter a protective potential range .
- **protective potential range**
  - A range of corrosion potential values in which an acceptable corrosion resistance is achieved for a particular purpose.
- **Q**
- **quench-age embrittlement**
  - Embrittlement of low-carbon steels resulting from precipitation of solute carbon at existing dislocations and from precipitation hardening of the steel caused by differences in the solid solubility of carbon in ferrite at different temperatures. Quench-age embrittlement usually is caused by rapid cooling of the steel from temperatures slightly below Ac_1 (the temperature at which austenite begins to form), and can be minimized by quenching from lower temperatures.
- **quench aging**
  - Aging induced by rapid cooling after solution heat treatment.
- **quench cracking**
  - Fracture of a metal during quenching from elevated temperature. Most frequently observed in hardened carbon steel, alloy steel, or tool steel parts of high hardness and low toughness. Cracks often emanate from fillets, holes, corners, or other stress raisers and result from high stresses due to the volume changes accompanying transformation to martensite.
- **quench hardening**
  - (1) Hardening suitable α-β alloys (most often certain copper or titanium alloys) by solution treating and quenching to develop a martensite-like structure. (2) In ferrous alloys, hardening by austenitizing and then cooling at a rate such that a substantial amount of austenite transforms to martensite.
- **quenching**
  - Rapid cooling of metals (often steels) from a suitable elevated temperature . This generally is accomplished by immersion in water, oil, polymer solution, or salt, although forced air is sometimes used.
- **R**

- **radiation damage**
  - A general term for the alteration of properties of a material arising from exposure to ioinizing radiation (penetrating radiation), such as x-rays, gamma rays, neutrons, heavy-particle radiation, or fission fragments in nuclear fuel material.
- **rare earth metal**
  - One of the group of 15 chemically similar metals with atomic numbers 57 through 71, commonly referred to as the lanthanides.
- **reactive metal**
  - A metal that readily combines with oxygen at elevated temperatures to form very stable oxides, for example, titanium, zirconium, and beryllium. Reactive metals may also become embrittled by the interstitial absorption of oxygen, hydrogen, and nitrogen.
- **recrystallization**
  - (1) Formation of a new, strain-free grain structure from that existing in cold-worked metal, usually accomplished by heating. (2) The change from one crystal structure to another, as occurs on heating or cooling through a critical temperature.
- **redox potential**
  - The potential of a reversible oxidation-reduction electrode measured with respect to a reference electrode , corrected to the hydrogen electrode, in a given electrolyte .
- **reducing agent**
  - A compound that causes reduction , thereby itself becoming oxidized.
- **reduction**
  - A reaction in which there is a decrease in valence resulting from a gain in electrons. Contrast with oxidation .
- **reference electrode**
  - A nonpolarizable electrode with a known and highly reproducible potential used for potentiometric and voltammetric analyses. See also calomel electrode .
- **refractory metal**
  - A metal having an extremely high melting point, for example, tungsten, molybdenum, tantalum, niobium, chromium, vanadium, and rhenium. In the broad sense, this term refers to metals having melting points above the range for iron, cobalt, and nickel.
- **relative humidity**
  - The ratio, expressed as a percentage, of the amount of water vapor present in a given volume of air at a given temperature to the amount required to saturate the air at that temperature.
- **residual stress**
  - Stresses that remain within a body as a result of plastic deformation .
- **resistance**
  - The opposition that a device or material offers to the flow of direct current, equal to the voltage drop across the element divided by the current through the element. Also called electrical resistance.
- **resistivity**
  - See electrical resistivity .
- **rest potential**
  - See corrosion potential and open-circuit potential .
- **riser**
  - (1) That section of pipeline extending from the ocean floor up the platform. Also, the vertical tube in a steam generator convection bank that circulates water and steam upward. (2) A reservoir of molten metal connected to a casting to provide additional metal to the casting, required as the result of shrinkage before and during solidification.
- **rust**
  - A visible corrosion product consisting of hydrated oxides of iron. Applied only to ferrous alloys. See also white rust .
- **S**
- **sacrificial protection**
  - Reduction of corrosion of a metal in an electrolyte by galvanically coupling it to a more anodic metal; a form of cathodic protection .
- **salt fog test**
  - An accelerated corrosion test in which specimens are exposed to a fine mist of a solution usually containing sodium chloride, but sometimes modified with other chemicals.

- **salt spray test**
  - See salt fog test .
- **saturated calomel electrode**
  - A reference electrode composed of mercury, mercurous chloride (calomel), and a saturated aqueous chloride solution.
- **scaling**
  - (1) The formation at high temperatures of thick corrosion product layers on a metal surface. (2) The deposition of water-insoluble constituents on a metal surface.
- **season cracking**
  - An obsolete historical term usually applied to stress-corrosion cracking of brass.
- **selective leaching**
  - Corrosion in which one element is preferentially removed from an alloy, leaving a residue (often porous) of the elements that are more resistant to the particular environment. Also called dealloying or parting. See also decarburization , decobaltification , denickelification , dezincification , and graphitic corrosion .
- **sensitizing heat treatment**
  - A heat treatment, whether accidental, intentional, or incidental (as during welding), that causes precipitation of constituents at grain boundaries, often causing the alloy to become susceptible to intergranular corrosion or intergranular stress-corrosion cracking . See also sensitization .
- **sensitization**
  - In austenitic stainless steels, the precipitation of chromium carbides, usually at grain boundaries, on exposure to temperatures of about 550 to 850 °C (about 1000 to 1550 °F), leaving the grain boundaries depleted of chromium and therefore susceptible to preferential attack by a corroding (oxidizing) medium.
- **shear**
  - That type of force that causes or tends to cause two contiguous parts of the same body to slide relative to each other in a direction parallel to their plane of contact.
- **shear strength**
  - The stress required to produce fracture in the plane of cross section, the conditions of loading being such that the directions of force and of resistance are parallel and opposite although their paths are offset a specified minimum amount. The maximum load divided by the original cross-sectional area of a section separated by shear.
- **sigma phase**
  - A hard, brittle, nonmagnetic intermediate phase with a tetragonal crystal structure, containing 30 atoms per unit cell, space group $P4_2/mnm$, occurring in many binary and ternary alloys of the transition elements. The composition of this phase in the various systems is not the same and the phase usually exhibits a wide range in homogeneity. Alloying with a third transition element usually enlarges the field of homogeneity and extends it deep into the ternary section.
- **sigma-phase embrittlement**
  - Embrittlement of iron-chromium alloys (most notably austenitic stainless steels) caused by precipitation at grain boundaries of the hard, brittle intermetallic sigma phase during long periods of exposure to temperatures between approximately 560 and 980 °C (1050 and 1800 °F). Sigma-phase embrittlement results in severe loss in toughness and ductility , and can make the embrittled material susceptible to intergranular corrosion . See also sensitization .
- **slip**
  - Plastic deformation by the irreversible shear displacement (translation) of one part of a crystal relative to another in a definite crystallographic direction and usually on a specific crystallographic plane. Sometimes called glide.
- **slow strain rate technique**
  - An experimental technique for evaluating susceptibility to stress-corrosion cracking. It involves pulling the specimen to failure in uniaxial tension at a controlled slow strain rate while the specimen is in the test environment and examining the specimen for evidence of stress-corrosion cracking.
- **slushing compound**
  - An obsolete term describing oil or grease coatings used to provide temporary protection against atmospheric corrosion .
- **smelt**

- Molten slag; in the pulp and paper industry, the cooking chemicals tapped from the recovery boiler as molten material and dissolved in the smelt tank as green liquor .
- **S-N diagram**
  - A plot showing the relationship of stress, *S*, and the number of cycles, *N*, before fracture in fatigue testing.
- **soft water**
  - Water that is free of magnesium or calcium salts.
- **solder embrittlement**
  - Reduction in mechanical properties of a metal as a result of local penetration of solder along grain boundaries.
- **solid-metal embrittlement**
  - The occurrence of embrittlement in a material below the melting point of the embrittling species. See also liquid metal embrittlement .
- **solid solution**
  - A single, solid, homogeneous crystalline phase containing two or more chemical species.
- **solute**
  - The component of either a liquid or solid solution that is present to a lesser or minor extent; the component that is dissolved in the solvent .
- **solution**
  - In chemistry, a homogeneous dispersion of two or more kinds of molecular or ionic species. Solution may be composed of any combination of liquids, solids, or gases, but they always consist of a single phase.
- **solution heat treatment**
  - Heating an alloy to a suitable temperature, holding at that temperature long enough to cause one or more constituents to enter into solid solution , and then cooling rapidly enough to hold these constituents in solution .
- **solution potential**
  - Electrode Potential where half-cell reaction involves only the metal electrode and its ion.
- **solvent**
  - The component of either a liquid or solid solution that is present to a greater or major extent; the component that dissolves the solute .
- **sour gas**
  - A gaseous environment containing hydrogen sulfide and carbon dioxide in hydrocarbon reservoirs. Prolonged exposure to sour gas can lead to hydrogen damage , sulfide-stress cracking, and/or stress-corrosion cracking in ferrous alloys.
- **sour water**
  - Waste waters containing fetid materials, usually sulfur compounds.
- **spalling**
  - The spontaneous chipping, fragmentation, or separation of a surface or surface coating.
- **spheroidite**
  - An aggregate of iron or alloy carbides of essentially spherical shape dispersed throughout a matrix of ferrite .
- **sputtering**
  - A coating process whereby thermally emitted electrons collide with inert gas atoms, which accelerate toward and impact a negatively charged electrode that is a target of the coating material. The impacting ions dislodge atoms of the target material, which are in turn projected to and deposited on the substrate to form the coating.
- **stabilizing treatment**
  - (1) Before finishing to final dimensions, repeatedly heating a ferrous or nonferrous part to or slightly above its normal operating temperature and then cooling to room temperature to ensure dimensional stability in service. (2) Transforming retained austenite in quenched hardenable steels, usually by cold treatment. (3) Heating a solution-treated stabilized grade of a austenitic stainless steel to 870 to 900 °C (1600 to 1650 °F) to precipitate all carbon as TiC, NbC, TaC so that sensitization is avoided on subsequent exposure to elevated temperature.
- **standard electrode potential**
  - The reversible potential for an electrode process when all products and reactions are at unit activity on a scale in which the potential for the standard hydrogen half-cell is zero.
- **strain**

- The unit of change in the size or shape of a body due to force. Also known as nominal strain.

- **strain-age embrittlement**
  - A loss in ductility accompanied by an increase in hardness and strength that occurs when low-carbon steel (especially rimmed or capped steel) is aged following plastic deformation . The degree of embrittlement is a function of aging time and temperature, occurring in a matter of minutes at about 200 °C (400 °F), but requiring a few hours to a year at room temperature.
- **strain aging**
  - Aging induced by cold working.
- **strain hardening**
  - An increase in hardness and strength caused by plastic deformation at temperatures below the recrystallization range.
- **strain rate**
  - The time rate of straining for the usual tensile test. Strain as measured directly on the specimen gage length is used for determining strain rate. Because strain is dimensionless, the units of strain rate are reciprocal time.
- **stray current**
  - Current flowing through paths other than the intended circuit.
- **stray-current corrosion**
  - Corrosion resulting from direct current flow through paths other than the intended circuit. For example, by a extraneous current in the earth.
- **stress**
  - The intensity of the internally distributed forces or components of forces that resist a change in the volume or shape of a material that is or has been subjected to external forces. Stress is expressed in force per unit area and is calculated on the basis of the original dimensions of the cross section of the specimen. Stress can be either direct (tension or compression) or shear. See also residual stress .
- **stress concentration factor (*K***
  - **$_t$).** A multiplying factor for applied stress that allows for the presence of a structural discontinuity such as a notch or hole; K_t equals the ratio of the greatest stress in the region of the discontinuity to the nominal stress for the entire section. Also called theoretical stress concentration factor.
- **stress-corrosion cracking (SCC)**
  - A cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. This excludes corrosion-reduced sections that fail by fast fracture. It also excludes intercrystalline or transcrystalline corrosion, which can disintegrate an alloy without applied or residual stress. Stress-corrosion cracking may occur in combination with hydrogen embrittlement .
- **stress-intensity factor**
  - A scaling factor, usually denoted by the symbol *K*, used in linear-elastic fracture mechanics to describe the intensification of applied stress at the tip of a crack of known size and shape. At the onset of rapid crack propagation in any structure containing a crack, the factor is called the critical stress-intensity factor, or the fracture toughness . Various subscripts are used to denote different loading conditions or fracture toughnesses:

    § **K_c**. Plane-stress fracture toughness. The value of stress int propagation becomes rapid in sections thinner than those in which plane-strain c

    § **K_I**. Stress-intensity factor for a loading condition that displac direction normal to the crack plane (also known as the opening mode of deforma

    § **K_{Ic}**. Plane-strain fracture toughness. The minimum value of K_c fo condition, which is attained when rapid crack propagation in the opening mod strain conditions.

    § **K_{Id}**. Dynamic fracture toughness. The fracture toughness dete loading conditions; it is used as an approximation of K_{Ic} for very tough materials

    § **K_{ISCC}**. Threshold stress-intensity factor for stress-corrosion crac strain stress intensity at the onset of stress-corrosion cracking under specified co

    § **K_Q**. Provisional value for plane-strain fracture toughness.

    § **K_{th}**. Threshold stress intensity for stress-corrosion cracking. The at the onset of stress-corrosion cracking under specified conditions.

§ **ΔK.** The range of the stress-intensity factor during a fatigue cycle

- **stress-intensity factor range, ΔK**
  - In fatigue, the variation in the stress-intensity factor in a cycle, that is, $K_{max} - K_{min}$.
- **stress-raisers**
  - Changes in contour or discontinuities in structure that cause local increases in stress.
- **stress ratio**
  - *A* or *R*. The algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are: (1) the ratio of the alternating stress amplitude to the mean stress, $A = S_a/S_m$; (2) the ratio of the minimum stress to the maximum stress, $R = S_{min}/S_{max}$.
- **stress-relief cracking**
  - Also called postweld heat treatment cracking, stress-relief cracking occurs when susceptible alloys are subjected to thermal stress relief after welding to reduce residual stresses and improve toughness . Stress-relief cracking occurs only in metals that can precipitation-harden during such elevated-temperature exposure; it usually occurs at stress raisers, is intergranular in nature, and is generally observed in the coarse-grained region of the weld heat-affected zone . See also cold cracking , hot cracking , and lamellar tearing .
- **striation**
  - A fatigue fracture feature, often observed in electron micrographs, that indicates the position of the crack front after each succeeding cycle of stress. The distance between striations indicates the advance of the crack front across that crystal during one stress cycle, and a line normal to the striations indicates the direction of local crack propagation. See also beach marks .
- **subsurface corrosion**
  - Formation of isolated particles of corrosion products beneath a metal surface. This results from the preferential reactions of certain alloy constituents to inward diffusion of oxygen, nitrogen, or sulfur.
- **sulfidation**
  - The reaction of a metal or alloy with a sulfur-containing species to produce a sulfur compound that forms on or beneath the surface on the metal or alloy.
- **sulfide stress cracking (SCC)**
  - Brittle failure by cracking under the combined action of tensile stress and corrosion in the presence of water and hydrogen sulfide. See also environmental cracking .
- **surfactant**
  - A surface-active agent; usually an organic compound whose molecules contain a hydrophilic group at one end and a lipophilic group at the other.
- **T**
- **Tafel line, Tafel slope, Tafel diagram**
  - When an electrode is polarized, it frequently will yield a current/potential relationship over a region that can be approximated by: $\eta = \pm B \log (i/i_o)$, where η is the change in open-circuit potential, *i* is the current density, and *B* and i_o are constants. The constant *B* is also known as the Tafel slope. If this behavior is observed, a plot on semilogarithmic coordinates is known as the Tafel line and the overall diagram is termed a Tafel diagram.
- **tarnish**
  - Surface discoloration of a metal caused by formation of a thin film of corrosion product.
- **temper**
  - (1) In heat treatment, to reheat hardened steel or hardened cast iron to some temperature below the eutectoid temperature for the purpose of decreasing hardness and increasing toughness. The process is also sometimes applied to normalized steel. (2) In tool steels, temper is sometimes inadvisably used to denote carbon content. (3) In nonferrous alloys and in some ferrous alloys (steels that cannot be hardened by heat treatment), the hardness and strength produced by mechanical or thermal treatment, or both, and characterized by a certain structure, mechanical properties, or reduction of area during cold working.
- **temper color**
  - A thin, tightly adhering oxide skin (only a few molecules thick) that forms when steel is tempered at a low temperature, or for a short time, in air or a mildly oxidizing atmosphere. The color, which ranges from straw to blue depending on the thickness of the oxide skin, varies with both tempering time and temperature.

- **tempered martensite embrittlement**
  - Embrittlement of ultrahigh-strength steels caused by tempering in the temperature range of 205 to 400 °C (400 to 750 °F); also called 350 °C or 500 °F embrittlement. Tempered martensite embrittlement is thought to result from the combined effects of cementite precipitation on prior-austenite grain boundaries or interlath boundaries and the segregation of impurities at prior-austenite grain boundaries.
- **temper embrittlement**
  - Embrittlement of alloy steels caused by holding within or cooling slowly through a temperature range just below the transformation range. Embrittlement is the result of the segregation at grain boundaries of impurities such as arsenic, antimony, phosphorous, and tin; it is usually manifested as an upward shift in ductile-to-brittle transition temperature. Temper embrittlement can be reversed by retempering above the critical temperature range, then cooling rapidly.
- **tensile strength**
  - In tensile testing, the ratio of maximum load to original cross-sectional area. Also called ultimate tensile strength.
- **tensile stress**
  - A stress that causes two parts of an elastic body, on either side of a typical stress plane, to pull apart. Contrast with compressive stress .
- **tension**
  - The force or load that produces elongation.
- **terne**
  - An alloy lead containing 3 to 15% Sn, used as a hot dip coating for steel sheet or plate. Terne coatings, which are smooth and dull in appearance, give the steel better corrosion resistance and enhance its ability to be formed, soldered, or painted.
- **thermal electromotive force**
  - The electromotive force generated in a circuit containing two dissimilar metals when one junction is at a temperature different from that of the other. See also thermocouple .
- **thermal embrittlement**
  - Intergranular fracture of maraging steels with decreased toughness resulting from improper processing after hot working. Thermal embrittlement occurs upon heating above 1095 °C (2000 °F) and then slow cooling through the temperature range of 815 to 980 °C (1500 to 1800 °F), and has been attributed to precipitation of titanium carbides and titanium carbonitrides at austenite grain boundaries during cooling through the critical temperature range.
- **thermally induced embrittlement**
  - See embrittlement .
- **thermal spraying**
  - A group of coating or welding processes in which finely divided metallic or nonmetallic materials are deposited in a molten or semimolten condition to form a coating. The coating material may be in the form of powder, ceramic rod, wire, or molten materials. See also flame spraying and plasma spraying .
- **thermocouple**
  - A device for measuring temperatures, consisting of lengths of two dissimilar metals or alloys that are electrically joined at one end and connected to a voltage-measuring instrument at the other end. When one junction is hotter than the other, a thermal electromotive force is produced that is roughly proportional to the difference in temperature between the hot and cold junctions.
- **thermogalvanic corrosion**
  - Corrosion resulting from an electrochemical cell caused by a thermal gradient.
- **threshold stress**
  - Threshold stress for stress-corrosion cracking. The critical gross section stress at the onset of stress-corrosion cracking under specified conditions.
- **throwing power**
  - (1) The relationship between the current density at a point on a surface and its distance from the counterelectrode . The greater the ratio of the surface resistivity shown by the electrode reaction to the volume resistivity of the electrolyte, the better is the throwing power of the process. (2) The ability of a plating solution to produce a uniform metal distribution on an irregularly shaped cathode . Compare with covering power .
- **tinning**
  - Coating metal with a very thin layer of molten solder or brazing filler metal.

- **torsion**
  - A twisting deformation of a solid body about an axis in which lines that were initially parallel to the axis become helices.
- **torsional stress**
  - The shear stress on a transverse cross section resulting from a twisting action.
- **total carbon**
  - The sum of the free carbon and combined carbon (including carbon in solution) in a ferrous alloy.
- **toughness**
  - The ability of a metal to absorb energy and deform plastically before fracturing.
- **transcrystalline**
  - See transgranular .
- **transcrystalline cracking**
  - See transgranular cracking .
- **transference**
  - The movement of ions through the electrolyte associated with the passage of the electric current. Also called transport or migration.
- **transgranular**
  - Through or across crystals or grains. Also called intracrystalline or transcrystalline.
- **transgranular cracking**
  - Cracking or fracturing that occurs through or across a crystal or grain. Also called transcrystalline cracking. Contrast with intergranular cracking .
- **transgranular fracture**
  - Fracture through or across the crystals or grains of a metal. Also called transcrystalline fracture or intracrystalline fracture. Contrast with intergranular fracture .
- **transition metal**
  - A metal in which the available electron energy levels are occupied in such a way that the ***d***-band contains less than its maximum number of ten electrons per atom, for example, iron, cobalt, nickel, and tungsten. The distinctive properties of the transition metals result from the incompletely filled ***d***-levels.
- **transition temperature**
  - (1) An arbitrarily defined temperature that lies within the temperature range in which metal fracture characteristics (as usually determined by tests of notched specimens) change rapidly, such as from primarily fibrous (shear) to primarily crystalline (cleavage) fracture. (2) Sometimes used to denote an arbitrarily defined temperature within a range in which the ductility changes rapidly with temperature.
- **transpassive region**
  - The region of an anodic polarization curve, noble to and above the passive potential range, in which there is a significant increase in current density (increased metal dissolution) as the potential becomes more positive (noble).
- **transpassive state**
  - (1) State of anodically passivated metal characterized by a considerable increase of the corrosion current, in the absence of pitting, when the potential is increased. (2) The noble region of potential where an electrode exhibits a higher than passive current density.
- **triaxial stress**
  - See principal stress (normal) .
- **tuberculation**
  - The formation of localized corrosion products scattered over the surface in the form of knoblike mounds called tubercles.
- **U**
- **ultimate strength**
  - The maximum stress (tensile, compressive, or shear) a material can sustain without fracture, determined by dividing maximum load by the original cross-sectional area of the specimen. Also called nominal strength or maximum strength.
- **underfilm corrosion**
  - Corrosion that occurs under organic films in the form of randomly distributed threadlike filaments or spots. In many cases this is identical to filiform corrosion .
- **uniaxial stress**
  - See principal stress (normal) .

- **uniform corrosion**
  - (1) A type of corrosion attack (deterioration) uniformly distributed over a metal surface. (2) Corrosion that proceeds at approximately the same rate over a metal surface. Also called general corrosion.
- **V**
- **vacuum deposition**
  - Condensation of thin metal coatings on the cool surface of work in a vacuum.
- **valence**
  - A positive number that characterizes the combining power of an element for other elements, as measured by the number of bonds to other atoms that one atom of the given element forms upon chemical combination; hydrogen is assigned valence 1, and the valence is the number of hydrogen atoms, or their equivalent, with which an atom of the given element combines.
- **vapor deposition**
  - See chemical vapor deposition , physical vapor deposition , and sputtering .
- **vapor plating**
  - Deposition of a metal or compound on a heated surface by reduction or decomposition of a volatile compound at a temperature below the melting points of the deposit and the base material. The reduction is usually accomplished by a gaseous reducing agent such as hydrogen. The decomposition process may involve thermal dissociation or reaction with the base material. Occasionally used to designate deposition on cold surfaces by vacuum evaporation. See also vacuum deposition .
- **voids**
  - A term generally applied to paints to describe holidays , holes, and skips in a film . Also used to describe shrinkage in castings and welds.
- **W**
- **wash primer**
  - A thin, inhibiting paint, usually chromate pigmented with a polyvinyl butyrate binder.
- **weld cracking**
  - Cracking that occurs in the weld metal. See also cold cracking , hot cracking , lamellar tearing , and stress-relief cracking .
- **weld decay**
  - Intergranular corrosion , usually of stainless steels or certain nickel-base alloys, that occurs as the result of sensitization in the heat-affected zone during the welding operation.
- **wetting**
  - A condition in which the interfacial tension between a liquid and a solid is such that the contact angle is 0° to 90°.
- **wetting agent**
  - A substance that reduces the surface tension of a liquid, thereby causing it to spread more readily on a solid surface.
- **white liquor**
  - Cooking liquor from the kraft pulping process produced by recausticizing green liquor with lime.
- **white rust**
  - Zinc oxide; the powdery product of corrosion of zinc or zinc-coated surfaces.
- **work hardening**
  - Same as strain hardening .
- **working electrode**
  - The test or specimen electrode in an electrochemical cell .
- **Y**
- **yield**
  - Evidence of plastic deformation in structural materials. Also called plastic flow or creep. See also flow .
- **yield point**
  - The first stress in a material, usually less than the maximum attainable stress, at which an increase in strain occurs without an increase in stress. Only certain metals--those that exhibit a localized, heterogeneous type of transition from elastic deformation to plastic deformation --produce a yield point. If there is a decrease in stress after yielding, a distinction may be made between upper and lower yield points. The load at which a sudden drop in the flow curve occurs is called the upper yield point. The constant load shown on the flow curve is the lower yield point.

- **yield strength**
    - The stress at which a material exhibits a specified deviation from proportionality of stress and strain. An offset of 0.2% is used for many metals.
- **yield stress**
    - The stress level in a material at or above the yield strength but below the ultimate strength , i.e., a stress in the plastic range.
- **Z**
- **zeta potential**
    - See electrokinetic potential .
